PROVINCIAL
MEDICAL & SURGICAL JOURNAL.

EDITED JOINTLY FOR THE
PROVINCIAL MEDICAL AND SURGICAL
ASSOCIATION.

BY

WILLIAM HARCOURT RANKING, M.D., CANTAB.,

AND

JOHN HENRY WALSH, ESQ., F.R.C.S.

1849.

LONDON: JOHN CHURCHILL, PRINCES STREET, SOHO.
WORCESTER: DEIGHTON AND CO., HIGH STREET.

INDEX FOR 1849.

A.

ABSCCESS, Post Pharyngeal, 638
 of the Pituitary Body, 107
 of the Spleen, 400
 Psoas, behind the Right Kidney, 714
Academie de Medecine, Paris, 21, 186, 245, 528, 577, 661, 692
 des Sciences, Paris, 23, 56, 187, 246, 529, 578, 665, 692
Address, Retrospective, of the Reading Pathological Society, 604, 633, 661
Adulteration of Food, 502
Air-Tractor, Dr. Simpson's, 223, 276
Albuminuria, Clinical Lectures on, 169, 203
America, Notes on, 106, 135, 190, 274, 525
American Estimate of Native Medical Literature, 196
Amputation, 21
 Spontaneous, in Utero, 215
Aneurism of Epigastric Artery, 193
 of Aorta, 271
 of Coronary Artery, Case of, 192
 of the Arch of the Aorta, 483
Anæsthetics, New, 98, 138, 139, 140, 166
Anæsthesia, Local, 187
Anus, Imperforate, 48, 215
Annuity Fund, Medical, 81
Animalcules in the discharges of Cholera, 578
Anniversary Meeting, Remarks on, 296, 463
 at Worcester, 421,
 at Hull, 474
Aorta, Wound of, 538
Apoplectic Cyst in Brain, 216
Apoplexy from Rupture of the Basilar Artery, 553
Appointments, 28, 56, 84, 112, 140, 168, 308, 363, 420, 560, 588, 615, 644, 699, 720
Areolar Sheath of Muscular Fasciculi, 499
Arrest of Development of both Bones of the Leg, 315
Arsenic, on the Sale of, 467
 Frequency of Poisoning by, 531
 in Sulphuric Acid, 718
Ascites, Case of, 540
Association, Internal management of, 403
 Powers and Responsibilities of, 493
Astragalus, Compound Dislocation of, 461
Atalectasis Pulmonum, 108
Autoplasty in Denudation of the Testicles, 714

B.

Benevolent Fund, Letters on, 305, 583, 643
 Remarks on, 308, 588

Biographical Notice of the late Dr. Streeten, 318
Birth Extraordinary, 279
Bladder, Ulceration of, 608
Bleeding and Low Diet, On the Effects of, on the Development of the Fœtus, 715
Blood Corpuscles of the Human Body, 107
 Tumour, New Treatment of, 164
 Arterial and Venous, 469
 Fibrin of, 471
Board of Health, Constitution of, 17
 Order from, 531
Bone, Medullary Substance of, 528
Bougie for Stricture, "Extrodution" of the, 717
Brain, Softening of the, 639
Branch Meeting, Bath and Bristol, 412, 551, 712
 Lancashire and Cheshire, 445
 North Wales, 546, 658
 South Eastern, 409, 495, 548
 South Western, 415
 Suffolk, 359
 Taunton and West Somerset, 415
 Yorkshire, 405
Bread for Diabetic Patients, 222
Bristol Medico-Chirurgical Society, 659
Brittan, Mr., Letter on his Discoveries, 584
Bronchotomy, 615
Bronchitis, Sub-acute, 316
 Pseudo-membranous, 527
Bronchocele, Case of, 516
Burns and Scalds, Inquiry on, 351
 Collodion in, 715
Burn, Extensive, treated with Nitrate of Silver, 569
Bursa, Dispersion of, 501

C.

Cæsarean Section, Cases of, 456, 469
Calomel in Chancre, 194
 in Febrile Diseases, 48
Camphor in Chloroform, 110, 179
Cannabis Indica in Menorrhagia, 333
Cancer of the Mamma, Mediastinum, and Pleura, 574
 Uterus, 234, 256
 Pylorus, 245
 Scrotum, 127
Carbonic Acid, Exhalation of, 191
Cases from Private Practice, 99, 119
Castration, Operation to supersede, 666
Cauterization of Poisoned Wounds, 246
Cerebellum, Tumour in, 608
Cerebral Abscess, 161
Cerebral Diseases of Infancy, 637,

Cervical Vertebrae, Dislocation of, 216
 Cervix Uteri, Neuralgia of, 470
 Charter of the College of Surgeons, Proposed new, 631, 710
 Cholera, Asiatic, Contagion of, 34, 62, 91, 108
 Assurance Society, 82
 Dr. Ayre's Treatment of, 630
 Fungoid Theory of, 631
 Inquiry on, 522, 633, 688
 Influence of, upon Pregnancy and the Fœtus, 715
 in America, 448, 475, 531, 699
 in Paris, 360, 608
 Letter on, 625
 Observations on, 7, 208, 268, 652
 On the Treatment of, 706
 Pathological Appearances in, 192, 500
 Progress of, 469
 Special Hospitals for, 518
 Treatment of, 109, 475
 Chloroform Inhalation, Remarks on, 52, 245
 in Surgery and Midwifery, 164
 Local Application of, 54, 195
 in Tetanus, 482
 Death from, 668, 698
 Chorea, Cases of, 105, 222
 Chronic Sciatica cured by the Actual Caution, 276
 Cirrhosis of the Lung, 468
 Clayicle, Treatment of Fracture of, by means of a New Instrument, 716
 Clinical Notes from Private Practice, 126, 316
 Clinical Illustrations, 234, 256, 486
 Coincidence between the Modern Treatment of Uterine Diseases, and that recommended by Hippocrates, 361
 Collodion in Fistulous Openings, 26
 in Burns, 715
 Corrigenda in Mr. Crouch's paper on Ovariectomy, 719
 Corroding Ulcer of the Uterus: Clinical Lecture on, 1, 179
 Concretion, Intestinal, case of, 9
 Concretions, Polypiform, 717
 Constitution of the Board of Health, 17
 Contagion of Asiatic Cholera, 34
 Congenital Glossocele, 109
 Cod-Liver Oil in Phthisis, 196, 335
 Dr. Ranking's Inquiries on, 214, 300, 356
 Creosote to Destroy the Taste of, 587
 College of Physicians: Lectures, 112, 224
 Cholera Report of, 643
 Surgeons, 56, 140, 196, 251, 279, 308, 335, 364, 420, 448, 476, 504, 588, 615, 644, 672, 700, 720
 Remarks on the Proposed New Charter of, 710
 Congenital Carcinomatous Tumour, 267
 Copaiba Capsules, Adulteration of, 644
 Coronary Artery, Aneurism of, 192
 Coroners and Medical Witnesses, 641
 Cotyledon Umbilicus in Epilepsy, 192, 289
 Cousins, Result of Marriage with, 447

Craniotomy, Remarks on, 490, 528
 Letters on, 494, 546, 572
 Creosote for Ulceration, 249
 as a Gargle, 250
 Croton Oil, Effects of, on the Human Hair, 98
 Croup, Case of, 160
 Tracheotomy in, 501
 Crystalline Lens, Absence of, 214
 Cynanche Pharyngea, from Disease of the Mucous Follicles, 24
 Tonsillaris, 486
 D
 Defective Utterance, Case of, 627
 Diagnostic Sign of Intermittent Fever, 24
 Digitalis, Recovery from, 278
 Distortion of Lower Extremity, 580
 Dislocation of the Humerus, 136
 Dispensing Medicine, On the Practice of, 419
 District Branches, On the Advantages of, 544
 Disorganization of the Kidneys, 78
 Diverticulum, Case of, 501
 Dropsy, Ovarian, 25
 Druggists, Illicit Practice of, 279
 Dysentery, Treatment of, by Injections of Nitrate of Silver and Creosote, 716
 E
 Empyema, Cases of, 153, 552, 608
 Empiricism at Cheltenham, 474
 Encephaloid Tumour of the Hand, 100
 Encephalitis, Case of, 488
 Epigastric Region, Morbid Condition of, 67
 Epilepsy, Cotyledon Umbilicus in, 192, 289
 Trephining for, 333
 Epidemic, Prevailing, Inquiry into the, 490
 Eruption, Peculiar, 567
 "Extroduction" of the Bougie for Stricture, 717
 F
 Fallopian Tube, Catheterism of, 472
 Falkner's Liquor Opii Sedativus, 28
 Femur, Resection of Head of, 530
 Fibrous Tumour of the Uterus, 234
 Fistulous Openings, Collodion in, 26
 Fleishy Tumour of the Pelvis, 302
 Foot torn off, 16
 Fork, passage of, through the Bowels, 501
 Foreign Bodies, Extraction of, from the Gullet, 666
 from the Meatus Auditorius, 694
 from the Vagina, 667
 Fracture of both Bones of the Leg, 238
 Oblique of Tibia, 239
 Transverse, of Femur, 294
 Compound, of Lower Jaw, 295
 Fulcrum, Mr. Gilbert's, 581

Fungus of the Spinal Dura Mater, 245
 Fungoid Tumours, 552
 Growths in Cholera, Letter on, 642
 Fungi, Choleraic, 610
 New Hypothesis for, 614
 Our Remarks on, 685, 697

G.

Gall-Stones, large number of, 328
 Generic Import and Development of the Upper Germi-
 nal Layers, On the, 715
 Genital Organs, New Structure in, 163
 Germinal Layers, On the Generic Import and Develop-
 ment of the Upper, 715
 Glossocele, Congenital, 109
 Glycerine, 502
 not a Remedy for Deafness, 502
 Grape Sugar in White of Egg, 276
 Gonorrhoea, Treated by Vinum Colchici, 610
 Gun-shot Wound, Cases of, 22, 26, 222

H.

Harveian Oration, 140
 Society, 699
 Heart, Investing Membrane of, 529
 Diseased, Cases of, 49, 498, 523, 575, 606
 Hæmoptysis, Fatal Case of, 183
 Hæmorrhage from the Bowels, 79
 Tongue, treated by Matico, 223
 Hernia Treated by Opium, 281
 Strangulated, Case of, 514,
 Clinical Lecture on, 791
 Herpes Zoster, Neuralgia following, 697, 718, 719
 Hiccup, Dry Cupping in, 530
 Hip-joint, Dislocation of, 569
 Homœopathy and Cholera, 587
 in Hydrophobia, 597
 Hospital Reports, Carlisle, 16, 17
 Essex and Colchester, 627
 Queen's, Birmingham, 100, 127,
 228, 294, 346, 488, 542, 570, 656
 South Staffordshire, 596
 West Norfolk and Lynn, 267, 683
 Hospital Gangrene, Treatment of, 163
 House-to-House Visitation in Cholera, Remarks on, 657
 Hunterian Oration, 56
 Human Hair, Effects of Croton Oil on the, 98
 Hypertrophy of the Left Ventricle of the Heart, 50
 Hydrocele, New Treatment of, 164, 250
 Hydrophobia Spontanea, 332
 Chloroform in, 596
 at Queenshead, Alleged case of, 597

I.

Ice for Uterine Contraction, 164
 Illicit Practice of Druggists, 279
 Ileum, Ulceration of, 79

Iliac Region, Tumour in the Right, 20
 Impaction of a Halfpenny in the Pharynx for eight
 months, 53
 Imperfect Urethra, 48
 Imperforate Anus, 48
 Intestinal Concretion, Case of, 9
 Inguinal Rupture, Case of Incomplete Reduction of, 41
 Incontinence of Urine, 51
 Infants, On the Diseases of, 71, 649
 Influence of Mother on Child, 124, 306
 Inflammation of the Cranial Bones, 137
 Intramural Interment, Petition against, 274
 Insomnia from Retained Biliary Secretion, 293
 Interview of the Deputation from the Committee of
 the Poor-Law Medical Officers with the Pre-
 sident of the Poor-Law Board, 329
 Infancy, Cerebral Diseases of, 637, 689
 Infantile Diabetes, Case of, 342
 Injuries of the Head, Observations on, 589, 645
 Insurance Offices, Fees to Medical Men, 644
 Intermittent Fever, New Diagnostic Sign of, 24
 Intra-Uterine Crying, 615
 Iodide of Potassium as a remedy for the Poisonous
 Effects of Lead and Mercury, 246
 Iris, Congenital Defects of, 512
 Iron Rod passed through the Skull, Recovery from, 333

J.

Jaw, Lower, Malignant Disease of, 49
 Jaundice, Nitrate of Silver in, 578

K.

Kidney, Tumour of the, 20
 Kidneys, Disorganization of, 78
 Diseased, 270, 607

L.

Laryngitis, Acute, Case of, 6
 Letter on, 55
 Larynx, Ulceration of, 269
 Lectures on Surgery, by G. M. Humphry, Esq., 29,
 57, 85, 113, 141, 197, 225, 281, 309, 393,
 449, 505, 561, 617, 673
 Lecture, Clinical, on Corroding Ulcer of the Uterus,
 Ulcerations of the Stomach, Tubercle and
 Melanosis of the Lungs, &c., 1
 Leg, Retraction of, Cured by Actual Caution, 304
 Lemon Juice in Rheumatic Gout, 109
 Literature of the Nineteenth Century, 27
 Life-Assurance Reports, Remarks on, 181
 Offices, Remuneration of Medical Men
 for Reports, 223, 251
 Among Medical Men, 187, 218
 Lime Water in Cholera, 560
 Lithotripsy, Successful Case of, 402

Limbs, on the Nature of, 470
 Local Application of Chloroform in Lumbago, 25
 Disease, Medical Treatment of, 231
 Lunacy, on Certificates in, 544, 613
 Lungs, Emphysematous, 713

M.

Masturbation, Sign of, 501
 Malformation of the Heart, 327
 Malignant Disease of the Lower Jaw, 49
 Ulceration of the Thumb, 249
 Management of the Journal, 349
 Matico for Hæmorrhage of the Tongue, 223
 Melanosis of the Lungs, Clinical Lecture on, 1
 Medico-Chirurgical Society, 168
 Medical Directory and Mr. Dawson's Pamphlet, 167
 447
 Decision in the County Courts, 140
 Reform, Remarks on, 188, 165, 223
 Memorial on, 194
 Fees at Coroner's Inquests, 611
 Legislation, Memorial on, 248
 Letter on, 273, 698
 and Surgical Association for Gloucestershire,
 Memorial from, 249
 Officers, Qualification of, for Parochial Offi-
 ces, 643
 Ethics, Remarks on, 348
 Means of Recognizing the Sensibility of the Retina in
 Certain Cases, 53
 Memoir on Turning, as an Alternative for Craniotomy
 and the Long Forceps in Deformity of the
 Brin of the Pelvis, &c., &c., 9
 Memorial to Sir George Grey, 328
 Menorrhagia, Oxide of Silver in, 578
 Cannabis Indica in, 333
 Thlaspi Bursa Pastoris in, 163
 Mesmerism, Remarks on, 125
 Meningeal Apoplexy in the Brain of an Infant, 328
 Meningitis, Cerebro Spinal, 699
 Meibomian Glands, Curious Secretion by, 542
 Microscopical Discoveries in Cholera, 559, 586
 Remarks on, 571
 Observations, Report of the Committee
 appointed at Bristol to conduct the, 600
 Midland Railway and Mr. Sands Cox, 75, 670, 694
 Minute Anatomy of the Air-Cells, 74
 Morbid Conditions of the Epigastric Region, 67
 Muscular Contractions after Death from Cholera, 665

N.

National Institute, 559, 663
 Naval Assistant Surgeons, Remarks on, 520
 Letter on, 582
 Neuralgia of the Penis, 470
 following Herpes Zoster, 697, 718, 719
 of the Cervix Uteri, 470

Neuralgia, Treatment of, 193, 697
 Intercostal, 692
 Nitrate of Silver, Priority of Application of, 461
 in Jaundice, 578
 Nineteenth Century, Literature of, 27
 Non-liability of Railway Companies for Professional
 Services performed in Cases of Accident;
 Cox v. the Midland Railway Company, 75
 Notes on America, 106, 190, 135, 274
 from a Practitioner's Day-Book, 136
 Notice of the late Dr. Prichard, 55
 Dr. Thackeray, 474
 Mr. Aston Key, 503
 Notices of the late Mr. Crowfoot, 83, 160
 to Correspondents, 28, 56, 84, 112, 140, 168,
 196, 224, 252, 280, 308, 336, 364, 392, 420,
 418, 476, 504, 532, 560, 568, 616, 644, 672,
 700, 720
 Nux Vomica in Diarrhoea, 109
 in Impotence and Spermatorrhoea, 610

O.

Obituary, 28, 56, 84, 112, 140, 168, 196, 224, 252,
 280, 308, 335, 364, 392, 420, 476, 504, 532,
 560, 588, 616, 644, 672, 700
 Objects of the Association, 296
 Oleaginous Aliments in Pththisis, 97
 Opium in the Treatment of Hernia, 287
 Ophthalmia, Granular, Treatment of, 530
 Osseous Tumours, 533
 Oxide of Silver in Menorrhagia, 578
 Ovarian Dropsy, 25
 Cyst, 103
 Disease, Case of, 217
 Ovariectomy, Remarks on, 130, 622
 Successful Cases of, 477, 523

P.

Pain, Diagnostic Value of, 137
 Pancreatic Juice, On the, 161, 246
 Papillæ of the Tongue, Structure of, 275
 Paracentesis Thoracis, Operation of, 484, 680
 Penis, Neuralgia of, 470
 Unusual Affection of, 692
 Pelvis, Abscesses of, 261
 Petition of Medical Officers of Unions, 246
 Pericarditis, Treatment of, 579
 Peyer's Glands, Ulceration of the, 269, 523
 Pessary Impacted within the Vagina, Cases of, 177, 680
 Perforating Ulcer of the Stomach, 77
 Pituitary Body, Abscess of, 107
 Phlebitis, Signs of, 553
 Phymosis, New Operation for, 193
 Pththisis, Oleaginous Aliments in, 97
 On the Influence of Pregnancy upon the
 Progress of, 715
 Plugging the Vagina in Uterine Hæmorrhage, 72
 Placenta Prævia, Case of, 178

Placenta, Diseased, 301
 Pleurisy, Latent and Circumscribed, with Effusion, 480
 Acute, 713
 Poisoning by Arsenic, 54, 72
 Poisons, Animal, Incubation of, 164
 Sale of, 588
 Poisoning by Opium, Galvanism in, 250
 by Sulphuric Acid, 250
 by Creosote, 250
 by Acetate of Lead, 266, 343
 by Lobelia Inflata, 335
 by Chloride of Zinc, 176
 Polypiform Concretions, 717
 Poor-Law Medical Committee, 23
 Relief, Letters on, 137, 273, 473,
 585, 613
 Officers, Meeting of, 47
 Remarks on, 76, 129, 133
 Practising Druggists, Letter on, 111
 Practical Observations on Cholera, 7
 Practical Observations, 539
 Process for the more Certain Detection of Arsenic, 55
 Proposed New Charter of the College of Surgeons, 710
 Prolapse of the Gravid Uterus during Labour, 53
 Pregnancy, Extra-Uterine, Case of, 186
 and the Fœtus, Influence of Cholera upon,
 715
 On the Influence of, upon the Progress of
 Phthisis, 715
 Pruritus Ani, *Spigelia Marylandica* in, 25
 Prosecution by the Society of Apothecaries, 224
 Probang, on the Use of, 595
 Public Medical Officers and the Medical Profession, 45

PROVINCIAL MEDICAL & SURGICAL JOURNAL.

A CLINICAL LECTURE,

DELIVERED AT THE LEEDS PUBLIC DISPENSARY.

By J. D. HEATON, M.D., Senior Physician
to the Dispensary.

CORRODING ULCER OF THE UTERUS; ULCERATIONS
OF THE STOMACH; TUBERCLE AND MELANOSIS
OF THE LUNGS; &c.

Mary Holmes, aged 61, a widow; has borne a family. She has supported herself by washing so long as she was able to work. She has been out of health for three or four years, during which time she has had much medical treatment from different practitioners, who have successively given her up without much benefit. For the last two years she has been confined to bed. She has been subject to large and repeated uterine hæmorrhages, during the intervals between which there has been a profuse uncoloured discharge from the vagina, which she describes as watery. She has had frequent pain in the uterine region and in the loins, but not very severe. She has, likewise, been subject to pain at the stomach, but not very severe. She has had much nausea and frequent vomiting. She has occasional attacks of severe cough, occurring from time to time, accompanied with considerable expectoration, but not bloody, and again subsiding. She is, likewise, subject to violent attacks of dyspnoea, amounting to orthopnoea, which leave her spontaneously after a time. She had a fit, which was called apoplectic, about twelve months since; and she has had several fits of a similar nature, more recently.

At the time that she came under my care, she was in a state of great debility and prostration; the face had a shrunken appearance, but was not very pale. She had much throbbing, and a confused sensation in the head; the memory was much impaired, and her answers to questions were uncertain and confused. The pulse was frequent, very small and feeble, occasionally almost imperceptible at the wrist; feet cold; some œdema of both hands and feet. Shortness of breath not very oppressive at this time, nor cough very troublesome. Slight wandering pains over the body, principally at the epigastrium; but little pain or tenderness in the hypogastric region. No uterine hæmorrhage at this time, nor for some time previously, but a considerable watery discharge *per vaginam*. Urine passed freely; bowels constipated; tongue clean and moist. Owing to the great prostration of the patient, no auscultation

of the thoracic organs was attempted; and all vaginal examination was absolutely disallowed.

The more immediate indication of treatment, in this case, was to revive the patient from the excessive state of prostration in which she was sunk, and to improve the quality of the blood deteriorated by frequent hæmorrhages and wasting discharges. Strong beef-tea and other nutritious food in a liquid form, were ordered for her diet, (wine would have been desirable had her circumstances enabled her to procure it,) the medicine was as follows:—

R. Mist. Ferri Co., oz. viij.; Tinct. Cardamomi Co., dr. vj.; Tinct. Hoscymi, dr. ij. M. Sumat oz. j., quater die.

R. Pil. Rhæi Co., gr. iij.; Pil. Hydrargyri, gr. ij. M. Fiat pil. hora somni sumenda.

This medicine agreed with her, and under this treatment, for a few days, she considerably improved. She had somewhat more power; the confusion and pain in the head were relieved, but the appetite was very poor, so that she took much less support than I should have wished, and the pulse was still very feeble.

The same treatment was continued; but, in a day or two afterwards she considerably deteriorated, much hæmorrhage again occurred, and returned several times; there was no perceptible enlargement over the uterus, and but little pain or tenderness. The bowels now became obstinately confined; mild remedies were used in the first place, and afterwards more active ones, but without success. Vomiting soon followed, and everything that was taken, either as food or medicine was speedily rejected, except one or two full doses of calomel, which remained, but did not produce any action of the bowels. This obstinate constipation and vomiting continued several days. Enemata were again expelled without producing any action, till one was administered containing two drops of croton oil, when much indurated fæces were evacuated, requiring, however, some mechanical assistance for their removal, owing to the great weakness of the patient. But the stomach remained incapable of retaining any food, though every means that could be suggested was tried for allaying its irritability; and this, together with continual returns of uterine hæmorrhage, reduced her to the last stage of prostration. She lingered a few days without much pain, the extremities lost all natural warmth, the pulse became imperceptible at the wrist, and she died of inanition about three weeks after her admission, and having been a fortnight almost without

any support, except a little brandy and water taken occasionally.

The examination was made forty-eight hours after death.

The body did not present a very emaciated appearance; there was but little oedema of the extremities. In the thorax, the lungs were free from pleuritic adhesions. The upper lobe of each lung had the surface irregularly puckered, and contained in its substance several of those hard circumscribed masses usually regarded as a chronic form of tubercular disease; but there were no softened tubercles, nor tubercular cavities. Of these masses, the smaller ones were dense and cartilaginous, and of the same dark colour throughout; the larger ones contained much earthy matter in the centre, of a grey colour; of these the largest was surrounded by a well-defined sac of false membrane, and contained in the centre a mass of solid earthy matter, of a drab colour, friable, but sufficiently hard to resist the knife. There were also a few small spherical masses of grey semi-transparent induration, about the size of a coriander seed, scattered through the substance of the lungs. In other parts, the substance of the lungs seemed to have its healthy structure, being soft and spongy, but very slightly crepitant, owing to an unusual dryness of the tissue, so that on making a section, scarcely any fluid would exude by pressure. A section presented an unusually dark colour, marbled with various shades of dark grey and purple. There were a few emphysematous dilatations along the margins of the lungs. In some of the bronchial tubes, the lining membrane was of a pale colour and quite healthy; in others it was red, thickened, and indurated; but the tubes were not dilated. Around the large bronchial tubes at the root of the left lung were several melanomatous tumours, some embedded in the substance of the lung, others upon the surface. These were rounded bodies from the size of a pea to that of a small grape, consisting of a membranous capsule, enclosing a dense black liquid, very much of the appearance and consistence of black paint, but not oily. One of the bronchial tubes was traced into one of these melanotic capsules, in which it seemed to terminate. Some bronchial glands were much enlarged, and filled with earthy matter, surrounded by a black melanotic substance, similar to that above mentioned, but more solid. The heart was somewhat hypertrophied, and there was some thickening and induration both of the aortic and mitral valves, slightly also of the tricuspid valve. In the abdomen, the stomach appeared large; the lining membrane presented no appearance of vascularity, and was unusually pale, except along the course of the larger curvature, which presented some irregular black patches; this discolouration was somewhat lessened by washing, but there still remained brownish black stains of the mucous membrane, which were quite permanent. Irregularly scattered over the surface of the stomach were numerous small circular ulcerations, of the size of the circumference of a pea, and smaller. These were superficial, not passing deeper than the mucous membrane, without any

thickening or induration of the edges, or vascularity around; the bottom of the ulcers was uneven, and generally stained of a black colour. Nothing remarkable was observed in the intestines or other abdominal viscera. The uterus was not above the ordinary size in females who have borne children. The neck of the uterus was entirely removed by ulceration, which had invaded likewise the body of the organ, spreading chiefly on the inner surface. The ulceration had a dirty brown colour, and an irregularly granular surface. The cavity of the uterus was occupied by a thick brownish red fluid. Preparations of the uterus, stomach, and lungs, are preserved in the museum of the Leeds School of Medicine.

The chief interest of this case depends on the *post-mortem* examination, which disclosed a combination of several morbid states of not very common occurrence. The most prominent disease, at the time of the patient's admission, was that of the uterus. Here there had evidently been serious disease for a long time. The frequent hæmorrhages, alternating with a thin watery discharge, and the age of the patient, might have led to the suspicion of cancer of this organ, but other symptoms did not agree with this supposition; there was not the severe lacerating pain of this disease; the pain in the uterine region was very mild and endurable, neither could any such enlargement and induration of the uterus as is usually perceptible in advanced cancerous disease be detected by the hand applied to the abdomen; the complexion, likewise, wanted the faded yellow tint generally considered so characteristic of the cancerous cachexia.

The frequent hæmorrhages, so long continued, rendered it highly probable, in the absence of the more exact proof by vaginal examination, that some form of ulcerative lesion existed; we have seen how much of the organ had been actually removed by this process of ulceration. There are different forms of ulceration of the uterus; the *os tincæ* is peculiarly subject to superficial ulcerations, consequent upon some permanent state of irritation, or low inflammation of the organ. The more general use of the *speculum* has latterly made the profession much better acquainted with this form of disease, and its frequent occurrence, upon which depends probably the larger proportion of the cases of leucorrhœa, menorrhagia, and dysmenorrhœa, which come under our notice. This affection is very common, but is very amenable to proper treatment. We are much indebted to the French physicians for our knowledge of this disease, and its mode of cure, and some English writers have recently directed the attention of the profession to this class of maladies; I may more particularly mention my friend Dr. Henry Bennet, whose long residence in the Parisian Hospitals afforded him the best opportunities of becoming acquainted with the French practice. Besides such treatment as may be suggested upon general principles, the more specific and important means for the cure of this affection is a slight application of caustic to the abraded surface, frequently repeated.

The acid nitrate of mercury is the caustic much employed in the French hospitals; I have tried both this and the nitrate of silver, and am inclined to give preference to the latter.

Besides this superficial inflammatory ulceration, which is a benignant disease amenable readily to proper treatment, the uterus is occasionally subject to a much more severe and intractable form of ulceration, frequently named corroding or phagedenic ulcer of the uterus, and of which the case we are considering furnishes a good example. This disease is sometimes spoken of as cancerous ulceration, but appears to me to differ essentially in its nature from cancer. In cancer we have the growth of a morbid tissue, which much augments the size of the organ attacked, and which may develop for a considerable time without any ulceration; but the disease of which we have here an example, *commences* with ulceration, which gradually destroys the substance of the organ, but without the formation of any morbid heterologous growth. The corroding ulcer of the uterus, when fully established, may correctly be termed a malignant disease, as it is very little amenable to treatment, and tends to advance progressively till it leads to a fatal result. It seems to be very similar to that malignant ulceration which we sometimes see on the cheek or side of the nose of elderly people, (not lupus,) which is here likewise frequently spoken of as cancer, but which seems to want the essential character of cancer,—viz., the growth of a new tissue, different from any proper to the healthy body. This disease may be distinguished from cancer of the uterus by vaginal examination, both by the touch, and by the use of the speculum. The uterus, in cancer, is much enlarged, and deformed; in this disease there is mere loss of substance. In advanced cancer a tumour may commonly be felt through the abdominal parietes. As the corroding ulcer usually attacks first the *os tincæ*, its existence may be readily ascertained by vaginal examination, but cases are described in which only the internal surface of the uterus has been attacked, and thus much of the substance of the organ has been destroyed, without any appearance externally. Here the exact diagnosis must be much more difficult, and the possibility of any effectual treatment much diminished. This disease, as well as cancer, is usually described as being accompanied with severe pain; in the case we are considering the pain was never very distressing, and I think it is always less acute in this disease than in cancer. The question has been entertained whether this phagedenic ulcer be of a syphilitic nature; I believe that this is not at all the fact; the general opinion of the most experienced practitioners is, that syphilitic ulcerations of the uterus are of very rare occurrence; venereal phagedena is much more rapid in its progress than is the disease we are considering; and, lastly, this disease occurs in persons without any suspicion of the venereal taint, as in the present instance.

The natural termination of the corroding ulcer of the uterus is in death, either by the gradual deterioration of the health and exhaustion consequent upon the

continued discharges, or sometimes more speedily by the ulceration perforating the peritoneum, and causing fatal peritonitis.

It is only when the disease is recognised in an early stage, that there is any hope of its cure, and at this early period it may be difficult to distinguish between this malignant form of ulcer, and those superficial ulcerations which I before mentioned. Indeed I think it not improbable that the latter may pass into the former, where proper treatment is neglected, and the organ continues exposed to whatever causes of irritation may have originally produced the complaint, and in a cachectic habit, where the functions of nutrition are inefficiently performed. It is evident that in the instance we have before us the disease was much too far advanced at the time of admission for the use of any curative means, even had permission been given for suitable examination; but when the ulceration is confined to the *os tincæ*, the proper treatment is free cauterization with one of the caustics I have before mentioned, together with constitutional treatment, to improve the general health, and promote nutrition. I had lately a patient having a large and deep ulceration of the *os tincæ*, with excavated edges, and which from her age and cachectic habit, I think would, most probably, if neglected, have assumed this malignant character, but which, under the treatment I have described, became completely cicatrized.

But besides the symptoms connected with the uterine disease, we had another class of symptoms referring to some disordered condition of the *primæ viæ*. These were,—the obstinate constipation which was at length overcome, and the constant vomiting of all ingesta, which continued till death. It was after the return of copious uterine hæmorrhage that the constipation occurred; this loss of blood would tend to repress the natural secretions, such as the bile and intestinal secretions, the proper stimulants of peristaltic action, and by which a soft consistence of the *fæces* is maintained. The great prostration of the patient prevented her making any effective voluntary efforts at defæcation; and, again, I think it not improbable that the coats of the rectum might have become permanently thickened and contracted by the long continued irritation occasioned by the proximity of the diseased uterus. We may add to these probable causes for the constipation, that the excessive irritability of the stomach coming on soon afterwards, so that all medicines, with the single exception of calomel, were speedily returned, prevented the effect of ordinary purgatives; so that I think we have a sufficient explanation of the constipation, which only yielded, at length, to the action of a powerfully stimulating injection; and still, her great weakness required some manual assistance for the removal of the hardened scybalæ. But in addition to this inactive state of the lower part of the canal, there was the morbid irritability of its upper extremity, the stomach. The true cause of this could only be conjectured during life; the frequent vomiting, which at length became so obstinate, and the occasional pain at the stomach, were symptoms such as might be expected to accompany this form of disease, but by

no means pathognomonic. A good deal of obscurity involves the history of these simple ulcers of the stomach; in some cases they are accompanied with symptoms such as in the present instance; in others they may go on to perforation of the stomach, causing fatal peritonitis, with no more marked symptoms than those of slight dyspepsia. Where we suspect their existence, the best treatment is by confining the patient to the mildest kind of diet, given in very small quantity at once. These ulcers are usually attributed to chronic inflammation of the mucous membrane, and where we see them surrounded by an increased vascularity, or with thickened edges, it is pretty evident that such is the true explanation; but in other cases, as in this, the surrounding mucous membrane appears in a healthy state, without any mark of inflammatory action, and then we can scarcely suppose that inflammation co-existed at the time of death, though, probably, ulceration cannot commence save in an inflamed tissue. The debility and anæmia of this patient must have strongly favoured the formation and continuance of these indolent ulcers. Perhaps we may fairly consider the ulceration of the uterus and of the stomach, as both favoured by the same constitutional imperfection.

I must say a few words upon the black stains which appeared on part of the inner surface of the stomach. Dark discolourations in this situation may depend upon different causes: blood extravasated under the mucous membrane, or congested in its vessels may assume a black colour, if acted on by any mineral acid; (if gastric juice be contained in the stomach, its muriatic acid may be sufficient to produce this effect;) sulphuretted hydrogen may also produce the same discolouration of the blood. But in this case, neither of these causes seems to have been in operation; the contents of the stomach were a small quantity of inodorous fluid,—free, therefore, from sulphuretted hydrogen, and apparently consisting only of a small draught of beer, which had been given to her at her own request a short time before she died. Besides the uniform appearance of the black patches, devoid of anything like the ramifications of vessels, and the general bloodlessness of the organ, are against the supposition of the stains being altered blood. I am inclined, therefore, to think that the black stains were of the nature of true melanosis; and this more especially as melanotic disease was distinctly evident in the lungs, and this morbid deposit has a tendency to appear in different organs in the same body.

In the lungs we found the marks of various pathological conditions,—melanosis, tubercular degeneration, chronic bronchitis, and emphysema. It is very common to find the lungs of elderly people, especially of such as have resided in a smoky manufacturing town like this, of a very dark slaty-grey colour. This is owing to the inhalation of carbonaceous particles, with which the atmosphere is loaded, into the lungs, where, being insoluble and therefore incapable of absorption, and not causing sufficient irritation to effect their removal by coughing, they gradually accumulate. It is the same cause which gives to the mucus of the nose the black

colour which you must all have observed, but which disappears during any temporary residence in a pure country air. This sort of accidental blackening of the lungs is called spurious melanosis. The blackening of the lungs in this case is much more deep and decided than we usually meet with from this cause, except occasionally in the lungs of a chimney sweep, stoker, collier, or other person constantly compelled by his occupation, to the inhalation of a very large proportion of solid carbon in the air he breathes, which was not the case with this patient.

True melanosis is a morbid secretion from the blood, deposited usually in the cellular tissue of different parts of the body, where it may be either diffused, or accumulated in masses, either solid, or liquid inclosed in cysts of condensed cellular tissue. The tumours at the root of the lung were evidently of this latter kind; and I think it not improbable that a similar deposit into the cellular tissue was the cause of the black colour of the lungs. Melanosis of the lungs may exist without any symptoms during life. Should the tumours enlarge so as to press upon surrounding parts, the symptoms will be such as from the pressure of any other enlargement; occasionally the tumours will ulcerate and may thus communicate with a bronchial tube, causing a sudden expectoration of black matter, which is very diagnostic. This seems to have been the case in the instance before us, as one of the bronchial ramifications was traced into a melanotic cyst, in which it terminated. The matter of melanosis is unorganized; and its chemical analysis shews a very large proportion of carbon. It was placed by Wardrop—who claims to have first noticed it,—amongst malignant diseases, but it presents none of the characters of malignancy; its mechanical pressure may derange the functions of adjacent parts, or may lead to ulceration. It seems reasonable to suppose that melanotic deposits depend upon an undue accumulation of carbon in the blood. There are two organs of the body, which constantly separate this element from the blood; the lungs discharge it into the air as carbonic acid; the liver pours out bile, a secretion containing a large proportion of carbon, into the intestines. Recent physiological and chemical observations lead to the belief that much of the biliary secretion is again absorbed with the food, but the carbonic acid of the lungs is all excreted. The most rational treatment, therefore, where we suspect the existence of melanosis, is to secure as healthy a condition as possible of the respiratory organs, and an efficient performance of their function, which may be further promoted by active exercise. Spirituous liquors should be forbidden, and those non-azotised principles, such as starch, sugar, and fat, which Liebig supposes serve chiefly for the supply of carbon for combustion, by the respiratory process, should be sparingly allowed, at the same time the functions of the liver, and of all secreting organs, should be maintained in as efficient a condition as possible.

The tubercular disease which we have seen in these lungs requires little comment. We frequently find such

appearances in the lungs of persons who have had no marked symptoms of consumption during life. Temporary derangements of the health, either general or local, have so far impaired the function of nutrition, as to lead to the deposit of that imperfectly organized substance which is the first form in which tubercle usually presents itself; but, there being no decided constitutional tendency, when the temporary cause is removed, the process of nutrition again assumes its normal character; and there may be some attempt at the removal, by absorption, of the unhealthy deposit which has been already formed. In these lungs we have seen three different morbid appearances, which are all of the nature of tubercle. There were grey miliary granulations, the form in which tubercular disease first appears; there were grey masses of induration, of a larger size, and more irregular form, consisting of the same cacoplastic lymph as the smaller granulations, and probably formed by the confluence of several of these into one mass, their dark colour being due to some melanotic intermixture, either of the true or spurious kind, which I have before described; and, lastly, in some of these larger masses, some absorption of the more organic constituent had been effected, leaving its earthy inorganic matter in a form resembling soft mortar. This partial absorption, together with the tendency to contract, which we always find in cacoplastic lymph, wherever deposited, causes the irregular puckering we have seen on the exterior of the lung, which may always be regarded as the mark of some tubercular disease existing within. The bronchial glands are very commonly the seat of tubercular disease, when this exists in the lungs; some of these glands, in this case, presented a similar appearance to that which I have last described in the lungs, only much blackened on the exterior by melanotic deposit.

The redness and thickening of the mucous membrane lining some of the bronchial tubes, are the ordinary marks of chronic bronchitis. There was some cough during the short time that this case was under my observation, and the report of her previous state represents the cough as having been severe, accompanied with much expectoration and oppressive dyspnoea. These are the usual symptoms of chronic bronchitis; but it is not improbable that the exacerbations of cough, dyspnoea, and expectoration, might be dependent upon temporary congestions of the lungs, producing the symptoms of what is called pituitous catarrh; or the attacks of dyspnoea may have been asthmatic.

The only other morbid appearance in the lungs which I have to notice, is that of the emphysematous vesicles seen upon the margins of the lower lobes. Probably a more careful examination of the tissue of the lungs, upon the surface of a section, after they had been suffered to dry in a state of full inflation, would have discovered that the air-cells were generally dilated, and perhaps their walls atrophied. The other morbid states which we have already observed in the lungs, are such as would strongly favour this emphysematous dilatation of the air-cells; the thickening of the lining of some of the bronchial tubes, and the condensation of part of the tissue of the lungs by tuberculous deposit,—

both must have had the effect of lessening the natural elasticity and permeability to air, of these organs, and thus the atmospheric pressure upon the cells of the healthy part during each expansion of the chest, must have been unduly great, so as, by its constant repetition, to cause that gradual but permanent dilatation of the cells which constitutes emphysema. This emphysematous state of the lungs would have the effect of increasing the dyspnoea arising from the other causes we have before considered.

The unusual dryness of the lungs which we have observed, must arise from a deficiency of the natural secretion of the bronchial tubes. I do not know how to explain this, unless it be that this secretion had been diminished, in common with others, owing to the failure of the proper amount of blood in the vessels, drained by the uterine hæmorrhage and serous discharges. When the blood is much reduced in quantity, the secretions which are formed from it must necessarily be deficient. It is true that the impoverished and watery condition of the blood which may be caused by excessive hæmorrhage, is not unfavourable to the effusion of serum into the cellular tissue, or from serous surfaces, constituting the various forms of dropsy; but then, in most cases, the absorbents, whose activity is increased by the removal of blood, rapidly absorb watery fluids from the stomach, so as to maintain the proper quantity of circulating fluid, though of a quality so dilute and attenuated, as shall readily again exude as dropsical effusions through the coats of the vessels. But, in this case, although the discharge continued, by which the volume of the blood was diminished, the supply from without, even of mere watery fluid, was almost cut off, the stomach having been scarcely capable of retaining any fluid for several days. I may notice, as perhaps being in favour of this explanation, that the œdema of the extremities which was observed when the case was first seen, had become diminished at the time of death.

The lesion in the valves of the heart is such as is very commonly found in elderly people; the enlargement of the heart was most probably consequent on this defect of its valves, which, either by obstructing the free current of the blood, or allowing some regurgitation, would throw an additional labour upon the organ, and thus cause its hypertrophy. These defects in the mechanism of the heart would give rise to murmurs accompanying its natural sounds, but they do not appear to have been in themselves sufficiently serious to be incompatible with a comfortable enjoyment of health.

The case is an interesting one, as presenting a considerable variety of morbid conditions. I have endeavoured, so far as I am able, to explain their true pathological nature, and to deduce likewise some suggestions for diagnosis and treatment, should similar cases present themselves in a less advanced stage; and this is the best use we can make of such cases as this, evidently far beyond the reach of cure when they first come before us.

CASE OF ACUTE LARYNGITIS, WITH OBSERVATIONS.

By GEORGE NORMAN, Esq., F.R.C.S., Senior Surgeon to the Bath United Hospital.

(Read at the Quarterly Meeting of the Bath and Bristol Branch of the Provincial Medical and Surgical Association, September 28, 1848.)

A gentleman, aged 48, had common sore-throat, with swollen tonsils, for five or six days previous to the 22nd of August, from which he had in a great measure recovered, when on the afternoon of that day he was attacked with the symptoms of acute laryngitis, which rapidly increased, and in the night Dr. Everitt, of Devizes, was called in to see him, by Mr. Anstie, who had previously attended him. At that time he had difficulty of breathing, hoarseness, cough, a copious expectoration of viscid mucus, and pain and tenderness in the region of the larynx. There was but little heat of skin; the pulse 90, and of moderate force, but there was great depression of the general strength, and much restlessness. Tartar emetic was ordered at short intervals, till full vomiting was produced, and afterwards in sufficient quantities to keep up a state of nausea. He was seen early in the following morning (the 23rd,) by Dr. Everitt and Mr. Anstie. There was no relief of the symptoms, and there was more fever. He was bled at the arm till slight syncope took place, and twelve leeches were afterwards applied over the larynx, which bled freely. He was ordered calomel and tartar emetic every hour. At noon he expressed himself confidently as feeling better, and he appeared so in many respects, but the improvement was not such as was desirable in a case of so much danger, and as there did not appear much scope for further treatment, it was thought that the time was arrived to consider the question of tracheotomy, and with that view I was sent for. Dr. Everitt saw him between two and three in the afternoon, when he was much the same. There was no discolouration of the face, nor any decided symptoms of the near approach of a state of asphyxia; between four and five, however, he died somewhat suddenly, some time before I got to Devizes. The only alteration that preceded his death was, that of great increase of restlessness, so that he could not be kept in bed.

The throat, larynx, and trachea, were examined a few hours after death. There was great redness of the fauces, but little swelling of the tonsils; the epiglottis thickened and greatly enlarged, projected above the basis of the tongue, and looked like an extraneous substance occupying the whole space of the pharynx; its edges were thickened, everted, and puckered up, so as to form a narrow serpentine canal, terminating in the rima glottidis, the aperture of which was diminished to the smallest size by the thickened and inflamed state of the lining membrane of the larynx. The inner surface of the trachea was red, but less so than that of the larynx. Spread over its surface was a thin layer of lymph, which could be stripped off like a membrane. All appearance of inflammation in the inner surface of the trachea ceased abruptly about two

inches below the larynx. Further examination of the body was not admissible.

Cases of acute laryngitis in the adult are rare, but I believe are generally, if not always, fatal; they differ from the croup of infants, in the absence of the sonorous metallic respiration, and of any appearance of suffocation, and also in the suddenness of the death, without the previous laboured and frequent breathing which belongs to the last stage of croup, and to bronchitis,—the symptoms being those of general distress and restlessness; great depression; an occasional gasping effort of inspiration, but without hurried breathing; a constant desire to change the position, and a leaden sunken hue of the countenance, but not the swollen or dark-coloured appearance of the features, as in suffocation. Such has been the case in all the instances of the disease which I have seen.

One of these occurred in a gentleman of about fifty, whom I saw two years ago. He was seized suddenly with difficulty of swallowing at his dinner, and thought some portion of his food had lodged in the throat. Soon after he had a hoarse cough, with painful, rather than difficult, breathing. He was bled, and was to have had leeches applied in a few hours after, with calomel and opium every hour, but he was so much relieved before the time for applying the leeches arrived, that they were omitted, and he appeared so much recovered, that all alarm had ceased on his part and that of the persons about him, but in the evening of the following day the symptoms again returned. He had the same restlessness and gasping inspiration that marked the case now related, and he died suddenly, having been just before walking about the room. The *post-mortem* appearances were the same as in the case just related.

I think it probable, from the suddenness of death in these cases, without any previous laborious breathing, that death is occasioned by the impediment to the escape of carbonic acid from the lungs, from the contracted state of the larynx, that there comes a point when the blood is so deteriorated, that it is no longer compatible with life, and that death ensues as suddenly, as if the person, from accident, had inhaled carbonic acid gas, instead of atmospheric air.

A great practical question in such cases is the propriety of tracheotomy, and seeing the inefficacy of other remedial means, and the suddenness of the fatal termination, I am inclined to think it affords the most probable chance of saving the patient; but then it should be employed in the early stage of the disease,—that is to say, as soon as the true nature of the case can be made out with confidence. The inflammation being confined to the larynx, and suddenly terminating at the upper part of the trachea, as in both these cases it did, would go to show that an opening into the trachea would be effectual, if performed early, and it might be very safely. No one would hesitate to have recourse to this operation, if an extraneous substance had accidentally got into the larynx or trachea; and no ill consequences have arisen when it has been done, nor do wounds made into the trachea, in attempted

suicide, add much to the danger, or afford any great impediment to recovery. I am therefore disposed to agree with the opinion of Dr. Everitt, that the early employment of tracheotomy in a similar case, would not only be justifiable, but would afford the most probable means of averting the fatal termination. In Dr. Everitt's case the operation would have been somewhat difficult, for the neck was very short and thick, the trachea lying very deep, and the space for cutting down on it being very limited, but on a thinner subject with a long neck, the trachea lies sufficiently superficial to be very easily and safely opened.

PRACTICAL OBSERVATIONS ON CHOLERA.

By JOHN ALLAN, Esq., Surgeon, R.N., Epsom.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

I trust that you will concur in opinion with me, that the following narrative of facts, relating to the successful treatment of cholera, well deserves a place in the *Provincial Journal*.

Having witnessed, with extreme pain, the ill success attending the treatment of this fell disease on its visit to England in 1832, I have been most anxious, since its threatened return, to gain practical information relating to it, from such of my professional friends as had enjoyed extensive opportunities of observing and treating it. Among these, Mr. Robert Stedman, of Great Bookham, Surrey, has kindly furnished a narrative of his experience, which is most interesting; since the treatment which he adopted, first in his own person, and afterwards in a large number of cases, was attended with unfailling, and, inasmuch as he did not lose a single patient, I may say, unequalled success. With Mr. Stedman's permission, I submit to the profession the substance of his narrative.

Mr. Stedman arrived off Calcutta in the early part of October, 1817, a few weeks after the cholera first broke out at Jessore. The ship, on board of which he was the appointed surgeon, was eleven days kedging up the Hoogly River, and, as each day's progress lessened the distance to the capital, so it increased the horrors of the spectacle presented by the numerous dead bodies floating, up and down, with the flux and reflux of the tides. Mr. Stedman was the first person in the ship who was attacked by the cholera, probably, as was strongly impressed on his mind at the time, because, as a professional man, he took more interest, than any other individual on board, in noticing the numbers, forms, colours, &c., of the dead bodies, and, particularly looking on, when any native was performing his duty, as police, in moving such of them as happened to get entangled, when the ship was at anchor, at the bows, by the cable, or otherwise. The Bengal papers of that period stated, that between two and three thousand dead were cast into the river in a week. Hence Mr. Stedman's exposure to a sufficient source of putrefying

animal effluvia to account for his being the first individual in the ship seized by the disease.

His plan of treatment was simple and bold, but most unequivocally successful, since he lost not one of the crew, amounting to forty-eight, all of whom, with only one single exception, had the disease, whilst other ships in the river lost many of their men. A Bristol ship, moored about two cable lengths higher up the stream, lost thirteen of her crew in the first fortnight after her arrival.

Mr. Stedman's sheet anchor and sole reliance was calomel. Having commenced dosing himself, and having repeated it to a successful issue, he followed the same plan in all the other cases as they occurred. He was, as it were, knocked down by the first seizure, and instantly rendered unable to go to the medicine chest. He requested the chief officer to go and weigh twenty grains of calomel for him. He replied that he would bring the calomel and the scales, but that he was not going to give such a dose as that. By the time he returned into the cabin, Mr. Stedman had incessant vomiting, but no power. He begged the officer to weigh twenty grains, and then to slip it off the scale upon his tongue. This done, the vomiting ceased for a short time, but not the cramps in the abdomen and limbs. On the recurrence of the retching, Mr. Stedman again, in less than ten minutes, requested to have twenty grains more. This checked all further vomiting, and, in one hour afterwards, still having spasmodic pains and drawings of the abdominal muscles, with heavings to vomit, he asked for twenty grains more. This, the first officer refused to have anything to do with, but the second officer and others standing around over-ruled the objection, and a third dose of twenty grains was given. Shortly after this Mr. Stedman was so far relieved as to be able to sit upright in the chair, and then they made him sip brandy and water. This warmed his stomach, and brought on re-action of the heart, and, although very feeble, with frequent cold sweats, for several days, he might be said to have been well next day, as he was able to walk about, and attend to his duty.

The second case occurred on the third day after Mr. Stedman's attack; and very rapidly all on board, with the single exception, already mentioned, of the chief officer, (who entirely escaped,) were seized. The captain, who had gone ashore, and remained there the whole time, also escaped.

To some of the men Mr. Stedman found it necessary to give to the extent of five doses, and, to one individual, six doses, of twenty grains each. In two instances he began with half-drachm doses. In all the cases this simple plan proved successful. The only adjuncts were brandy and water, and, as soon as the appetite could take it, solid food well spiced. What seems still more remarkable, when one considers the habits and mode of living of the natives, is, that the same treatment proved equally successful with them. The native boat, called "The Dingy," employed to convey messages, persons, &c., to and from the shore to the ship, frequently brought alongside, friends or relations of the boatmen, for the doctor's advice and medicines. To these

Mr. Stedman gave his never-failing powders. Some of them he saw no more of, nor could he ascertain that any one of them died. On the contrary, the boatmen continued to bring more patients, or begged for powders for those who were too ill to be brought to the ship. To show his thankfulness and gratitude for the benefits conferred on his friends, the boat-master brought to Mr. Stedman, as a present, a string of beads, such, as he said, were worn only by Brahmins of high caste.

In 1832, Mr. Stedman was settled in private practice at Seven Oaks, in Kent, and, in the few cases of the cholera which then came under his care, he employed the same remedy, with the same success in every case.

It might be feared that the administration of so much calomel might cause severe salivation, at least, if not otherwise damage the constitution, and leave the patients ruined in health, and unfit for their usual pursuits. These results, however, were not experienced in any of the cases. Mr. Stedman himself, and all the people in the ship, were, sooner or later, in no long time restored to the enjoyment of their usual health and strength. Not one was severely salivated nor disabled from pursuing his usual vocation.

I refrain from entering here into the question of the contagiousness of cholera, upon which Mr. Stedman has, upon good grounds, formed a decided opinion, in which I concur, that it certainly is the product of a specific poison. As, however, these observations may be in the hands of professional men in remote districts, where they may be required, on the spur of the moment, to prescribe for the disease, it must be a satisfaction for them to know one remedy to which they may resort with some confidence of a successful issue. A case, which occurred about a fortnight ago, in this place, may serve to show what may be effected.

A woman 44 years of age, of feeble constitution, and who, some six years ago had suffered a slight attack of paralysis, after feeling languid and ill for a day, was suddenly seized in the middle of the night, with violent vomiting and purging, with most severe pains and cramps of the bowels and lower limbs. About nine o'clock in the morning, her medical attendant having been called to her, found her with shrunk and leaden visage; hands, feet and face shrivelled and cold; vomiting and cramps incessant; the regular rice-water stools passing from the bowels in quantities; pulse at the wrist scarcely perceptible. As this occurred in my near neighbourhood, her medical attendant, knowing I took particular interest in the subject, kindly requested me to see the patient with him. We immediately sprinkled fifteen grains of calomel upon her tongue, and gave directions that a second dose to the same amount, should be given in case the vomiting should recur within an hour. We applied a strong embrocation, containing Liq. Ammon., Ol. Terebinth. and water, to the abdominal surface, and bottles of hot water to the feet, and ordered the limbs to be diligently rubbed till warmth returned. The second dose of calomel was given within the hour. After this the vomiting and purging ceased, reaction gradually returned, and the cramps became less and less frequent and severe. The patient partook of

brandy and gruel, as soon as she could receive it. Towards afternoon the next day, the bowels not having acted, a mixture containing small doses of Epsom salts and henbane was given. When the bowels acted, they yielded stools at first black like tar, and afterwards green and most offensive. The result was that the poor woman was restored to her usual health in the course of a few days. Her gums were affected by the mercury, but only in a moderate degree.

It will be observed that in Mr. Stedman's hands, calomel was the sole remedy. The patients were not stimulated by spices and cordials, nor nauseated by antimonials, nor stupefied by opiates. The objects aimed at were to tranquillize the stomach, and disgorge the liver. These two objects accomplished, brandy, diluted with water, was gratefully taken.

I wish not to be mistaken and represented as affirming that no other mode of treatment has ever been useful and successful in cholera. I venture simply to affirm that I have not yet heard of any method that has been attended with such unqualified and unfailing success.

I do not wish to add to the length of this communication by any disquisition on the pathology of cholera, but it is impossible to see a simple remedy act so effectually without one's thoughts being turned to its *modus agendi*. Calomel, when rapidly diffused over the mucous surfaces of the tongue, fauces, œsophagus, and stomach, appears to exert a soothing or sedative influence, at least, over the disposition to vomit. When it reaches the duodenum, it seems to act as a powerful emulgent of the liver. As soon as the bile begins to flow, the blood in the vena portæ, previously stagnant, is set in motion towards the liver, followed, of course, by that in the mesenteric veins. The purging is thus arrested, apparently by the power of the calomel; for there would appear to be this essential distinction between cholera, and diarrhœa, or the ordinary purging produced by medicines, that, in these latter, the fluids evacuated are poured out by the exhalant arteries opening into the bowels, being a natural function unduly increased; whereas, the rice-water dejections characteristic of cholera, are, in fact, the liquid portion of the blood squeezed in a retrograde course out of the valveless mesenteric veins, through the open mouths of their minute extremities into the intestines, it being their healthy function to imbibe and absorb, instead of exhale fluids.

The free secretion and flow of bile being established by the peculiar action of the calomel, the blood in the abdominal veins resumes its healthy course towards the liver; the heart and lungs, both by nervous sympathy, and by the mechanical impulse thus given to the almost stagnant blood, participate in the relief, and thus healthy reaction is speedily established throughout the system.

JOHN ALLAN.

Epsom, December 18, 1848.

CASE OF INTESTINAL CONCRETION.

By SAMUEL S. DYER, Esq., Surgeon, Ringwood.

George Wills, aged 14 years, October 11th, 1848. Ever since birth he has, more or less, suffered from irregularity of the bowels, the excretions generally consisting of small and hardened scybala. At five years of age he had a more than usually severe aggravation of symptoms, nothing passing his bowels for a fortnight. At this time an artificial anus was proposed by the surgeon in attendance, but objected to by the parents. They have been constantly in the habit of giving him enemata of soap and water, or gruel.

He is now suffering great pain, recurring with greater severity at intervals of a few minutes; nausea, but no vomiting; the abdomen tympanitic, and enormously distended, measuring 39 inches round on a level with the umbilicus. The cavity of the thorax is diminished by upward pressure of the diaphragm, producing dyspnœa. There has been no relief from the bowels for the last three days. No tumour of any kind in either groin; unusual resonance on percussion in each lumbar region. On examination per rectum, I could distinguish, high up, some hardened fæces, and by this means removed as much as I could reach.

Small doses of Sp. Terebinth, with Tinct. Opii, were given to relieve pain and flatulence; and fomentations, and injections of warm water, which, however, returned without any fæculent matter. The long tube of O'Beirne could not be passed higher than five or six inches.

Oct. 12th and 13th. Symptoms continuing; still unable to reach or remove any fæces. Vomiting, hiccup, increasing pain; and early on the morning of the 14th, he died.

Post-mortem 28 hours after death.—Parietes of abdomen very much attenuated; signs of former and recent peritonitis; no enlargement of mesenteric glands. The entire intestinal canal greatly distended with flatus, one convolution alone, ascending, crossing and descending, as large as a man's thigh being all that appeared on turning back the parietes. In the sigmoid flexure of the colon and upper part of the rectum, was an enormous mass as hard as bone; this being removed from its position, and its enveloping intestine opened, appeared a mass of concreted or hardened fæces, measuring four inches long, and nine round, of greenish-brown colour, velvety feel, and covered with thick mucus.

As I know from two years personal experience that this boy had been as large as a woman in the last month of utero-gestation, it is not unreasonable to suppose that such a concretion had existed here, forming an obstruction from that time at least, if not from the date of the illness, nine years since. The pathological and practical questions which are suggested by this interesting case are, first,—What was this concretion? Was it formed of the husks or beards of some grain interwoven and matted together, as detected and explained by Dr. Wollaston and Mr. Clift? Or was it that the fluid part of the fæces had always of late years been absorbed? Its appearance very closely resembled the description of the former as given by Dr. Watson in his lectures, and I should have inclined to the opinion

of this being the true nature of the concretion had not the mother assured me the child had never eaten any oatmeal or barley meal, &c. Next, did the small quantity of alvine discharge come from the lower end of this mass separating, a fresh supply always accumulating above, or could it have remained in the same condition throughout, all excretions passing between it and the bowels?

Presuming no cathartics should be administered, under the almost certain belief that a mechanical obstacle was the cause of obstruction, should more violent means have been made per rectum, for its removal, or should we be justified in exploring the sigmoid flexure with scoops, and such like, or in making an artificial anus, as once proposed in this very case, had the parents consented, with (in addition to the filthy nuisance of such a supernumerary aperture,) the possibility of the recurrence of such symptoms?

MEMOIR ON TURNING,

AS AN ALTERNATIVE FOR CRANIOTOMY AND THE LONG FORCEPS, IN DEFORMITY OF THE BRIM OF THE PELVIS, &c. &c.*

By J. Y. SIMPSON, M.D.,

Professor of Midwifery in the University of Edinburgh.

SECTION IX.—ON THE COMPARATIVE DANGER OF LOCAL LESIONS OF THE MATERNAL ORGANS (VAGINA AND UTERUS,) IN DELIVERY BY TURNING, AND DELIVERY BY INSTRUMENTS.

As far as the observations in the preceding section go, they refer to the comparative degree of actual danger to the *life* of the mother under the opposite means of treatment, by which cases of labour, with arrestment of the head, and distortion of the pelvic brim, may be treated. They refer merely to the question of the probable death or probable survival of the mother, under the two different lines of practice spoken of,—viz., delivery by instruments, and delivery by turning. But it is possible, that, under such a form of labour as we have been considering, the mother may survive, that she may escape with life, and yet the maternal passages and neighbouring soft parts may be so much damaged and injured, as to interfere, in a more or less dangerous or distressing manner, with the state of her future health and future happiness. The cervix uteri, or the walls of the vagina, are sometimes so contused, or become so inflamed, that gangrene and sloughing supervenes, and lead on to the formation of cicatrices and strictures; or, what is still more deplorable, this resulting gangrenous inflammation may produce fistulous communications between the vaginal canal, and the rectum, or urethra, or bladder. No consequence could be possibly more deplorable than this last,—the occurrence of recto-vaginal or vesico-vaginal fistulæ.

* Continued from page 541 of last volume.

Speaking of sloughing of the urethra or neck of the bladder, as a consequence of severe labour, Dr. Collins remarks, in words dictated by the best possible feelings: "I do not know of any occurrence more calculated to reader the patient's life one of endless sorrow; or, at the same time, more likely to cause the practitioner such lasting regret. When it unfortunately happens (as in some instances is unavoidable,) in consequence of the protracted length to which we are at times compelled to permit the labour to proceed, owing to great difficulty in the passage of the head, the child being *alive*, here the medical attendant's mind cannot, on his *own* account, feel distressed, as the *only* means he could adopt to guard against the danger would be to lessen the head, which, in my opinion, no consideration should induce him to do under such circumstances."*

Are such distressing results as Dr. Collins here describes more liable to occur under the present practices of delivery by instruments, or under the new practice which I propose of delivery by turning? In other terms the question which I wish to consider is this:—

Are Local Lesions from Inflammation of the Vagina, such as Sloughing, Fistulæ, &c., more liable, in a Contracted Pelvis, to supervene after Delivery by Turning, or Delivery by Instruments?

Vaginal inflammation terminating in sloughing, cicatrices, and fistulæ, is not unfrequently observed after protracted labours that are terminated by the forceps or crotchet. In his "Clinical Midwifery," after detailing "the histories of fifty-five cases of difficult parturition in which the forceps was employed," Dr. Lee remarks, (p. 32,) "Five of the mothers whose cases have now been related died from puerperal convulsions, and four from the rash and inconsiderate use of the forceps; seven had the perineum more or less injured; one the recto-vaginal septum torn; five were left with cicatrices of the vagina after sloughing; and one with an incurable vesico-vaginal fistula." After describing the histories of sixty-five cases of "difficult labours from distortion of the pelvis, swelling of the soft parts, convulsions, hydrocephalus in the fœtus," and other causes in which delivery was effected by the operation of craniotomy," Dr. Lee again observes (p. 59,) "In thirty-eight of the cases in this report, the labour continued from forty to seventy hours. In the cases of spontaneous rupture of the uterus and convulsions only was the delivery effected before the labour had lasted upwards of thirty hours. In a very large proportion of the cases, the difficulty arose from distortion, or a contracted state of the pelvis. Rupture of the uterus took place in three before perforation, and the inflammation and sloughing of the uterus, vagina, and bladder, which proved fatal to eight others,

were chiefly or solely produced by the long-continued violent pressure on the soft parts by the head of the child before it was opened and extracted. In those who recovered with vesico-vaginal fistulæ, or contraction of the vagina from cicatrices, the unfortunate occurrences arose from craniotomy being too long delayed."

In the table which I have previously given from the same author (see Table IX.) of the results of 87 cases of craniotomy, local lesions on the part of the mother are noted as having occurred in several instances. Out of the 87 cases, eight,* or about 1 in every 10, suffered from vaginal inflammation and sloughing; four,† or nearly 1 in every 20, were left with vaginal fistulæ.

On the other hand, I am not aware of a single recorded instance in which vaginal sloughing and fistula ever followed transverse presentations of the fœtus, and where the delivery is, as a general rule, always accomplished by turning. Two circumstances lead to this immunity:—

1st. In presentations of the arm and shoulder the presenting part does not so completely fill up and compress the tissue of the brim as in head-presentations. Hence both the tendency to, and the occurrence of, congestion of the vessels and inflammation in the tissues, situated below the site of the compression,—viz., the vagina, &c., is far rarer. But,—

2ndly. The delivery is always, or almost always, accomplished early in the labour, and no doubt the mere length and protraction of the labour is one of the great, if not the greatest, predisposing and exciting causes of gangrenous inflammation and sloughing of the vagina.

In many cases vaginal sloughings and fistulæ have been attributed to the use of instruments, when they were more truly owing to gangrenous inflammation and sloughing, ensuing in consequence of the delay that was allowed to occur before instrumental delivery was adopted. In the history of most instances of vesico-vaginal and recto-vaginal fistulæ following labour, there is one simple fact, proving that they are not the direct effect, as is too often supposed, of lesions and lacerations by the forceps or crotchet. If vesico-vaginal fistulæ were, in this way, the direct effect of injuries produced by cutting with the instruments, then escape of urine through the vagina would be observed immediately after labour. But this is rarely the case; the general fact being, that the escape of urine through the false opening between the urinary and vaginal canals, is not seen for several days after delivery; because it is not till several days have elapsed that the gangrenous slough in the parietes of these canals separates. No soft parts, any more than the maternal canals, could stand, without endangering their vitality, the steady pressure upon them for twenty or thirty hours of a firm body, such as that which the

* Practical Treatise, p. 359.

* See Cases x., xx., xxx., xxxii., lvii., lviii., lxi., lxxiv.

† See Cases i., lii., liii., lxiv.

detained foetal head exerts in contracted pelves upon the two points of contraction,—the symphysis pubis before, and the promontory of the sacrum behind. It is not a matter of wonder that the soft structures compressed at these special points between the foetal head and maternal bones, should sometimes inflame and slough. It is, perhaps, surprising rather, that this consequence does not follow oftener. On this point Dr. Beatty, of Dublin, makes one or two remarks of such importance, that I will offer no apology for quoting them at length. "With respect (says he,) to laceration and sloughing of the vagina, bladder, &c., stated by some authors to be caused by the forceps, and used as an argument against their employment, I am of opinion that in the majority of cases, when these lamentable results occur, the blame is unmerited; because I have seen the worst inflammation and sloughings of these parts follow in cases where the perforator had been used, and even in some where no instrument whatever was employed. The truth is, the mischief is effected by the pressure of the infant's head upon the soft parts of the mother, and after this has been continued with sufficient intensity, for a sufficient length of time, the inflammation caused thereby will run its course, no matter in what way delivery is accomplished, whether by the natural efforts or by instruments. But it frequently happens that delivery is effected in these cases by instruments, *too late* to prevent the unhappy results alluded to, and then the operation is charged with the consequences. If an accurate account of the subsequent condition of all women after delivery could be obtained, I much fear that the histories of those cases in which labour had been allowed to run too long before interference was used, would be anything but satisfactory. The lamentable sloughings of the vagina, with subsequent closure of the passage by the process of cicatrization, or the still more distressing sloughing of the bladder, with its attendant urinary fistulæ, are seldom mentioned in lying-in hospital reports, because the patients are usually removed from those institutions *before* such results have become very apparent; and thus, a case left to nature, in which delivery is effected by the natural efforts, is set down as a favourable one, without any notice of its consequences."*

Dr. Beatty elsewhere soundly and correctly remarks in regard to the causation of gangrene and sloughing, &c., of parts of the vaginal walls by the pressure of the child's head, "that it is the *continuance* of the pressure that does the mischief rather than its *intensity*. We know that the soft tissues of the body are endowed with a resiliency—a power of resistance that enables them to bear a temporary compression of great amount without injury, while inferior pressure continued for a length of time will terminate in their disorganization. The malingering soldier is well aware of this fact, and acts upon it when he wishes to produce an ulcer. He

straps a piece of coin or other hard substance tightly upon the part. At first no effect is produced, and if the apparatus is removed in a short time, there is no evil consequence; but if the same amount of pressure is continued for some hours, such a degree of injury is inflicted as terminates in the destruction of the part, and a sloughing ulcer is the result."*

That the mere morbid protraction of labour is the great predisposing cause of gangrenous inflammation and sloughing of the vagina (as suggested in these remarks,) is shewn by Dr. Collins' results. Dr. Collins has recorded the duration of the labour in six cases where sloughing of the vagina was detected after death. The following table shews that the accident occurred in an immensely greater proportion in prolonged than in short labours; and that, consequently, protraction is, as I have just stated, almost a necessary antecedent to the occurrence. The case, I may remark, in which sloughing followed a labour less than twenty-four hours in duration required instrumental delivery, but the mode of delivery, whether by the crotchet or forceps, is not specialized by Dr. Collins. (See Practical Treatise, p. 358.)

TABLE XIV.

Duration of Labour in six Fatal Cases of Sloughing of the Vagina.

<i>Length of Labour.</i>	<i>Number of Deliveries.</i>	<i>Number of Cases.</i>	<i>Proportion of Cases.</i>
Within 24 hours	15,586	1	1 in 15,586
Beyond 24 hours	264	5	1 in 53

If, as these data shew, the protraction of labour is a main and almost necessary element in the production of gangrenous inflammation of the vagina, it is equally evident that turning, in the class of cases we are considering, while it frees the mother from the danger of a fatal termination, (as shewn in the last section,) would at the same time free her also from the chance of suffering from these *local* complications that are apt to follow upon protracted labours.

In the passage which I have quoted from Dr. Collins, at the commencement of the present section, that experienced practitioner laments our being occasionally compelled to subject our patients to the chance of local dangers and complications, in consequence of our being compelled, in some unavoidable instances, to allow the labour to proceed onward to a protracted degree, from the child being still alive, "for then the *only* means the practitioner could adopt to guard against the danger would," says Dr. Collins, "be to lessen the head, which, in my opinion, no consideration should induce him to do, under such circumstances," viz., as long as the infant is still living. The proposition which I have made of turning in such instances resolves the difficulties attending upon them in two

* Dublin Journal of Medical Science, Vol. xii., p. 290.

* Dublin Quarterly Journal, Vol. xxi., p. 344.

ways. For, *first*, it enables us to deliver the patient early and at once, and thus frees us from the dread of these consequences of protraction; and, *secondly*, the continued vitality of the infant would, under the treatment by turning, not be a reason and incentive for our dangerously delaying the delivery, but would form a strong reason and incentive for our proceeding with the practice at as early a period as was proper and possible. The details of a case or two may enforce these observations; and I shall select some from Dr. Collins, calculated both to illustrate these remarks, and to shew, that in protracted labours, occasionally *before* the time that the child does at last die, the dreaded amount of local mischief has been accomplished, so that if we waited always for the certainty of the infant's death, in order to deliver by craniotomy, we should wait beyond the time that was necessary, in order to save (locally,) the maternal structures from inflammation and gangrene.

It will be remarked, that in the first of the following instances, the foetal heart was heard six hours, and in the second case, eight hours, before delivery, and consequently ceased some time between these periods and the period at which the perforator was used—in short, necessarily not long before craniotomy was practised. Consequently we have here cases which, in the severity of their local, and, I may add, in the severity also of their general symptoms, shew what I have before argued, that the mother may herself be assuredly placed in the greatest possible danger and hazard from the protraction of the labour, before that protraction kills the child. I may add that, in the first case, the position of the foetal heart,—viz., in the right iliac region, shewed the infant to be in the occipito-posterior position, (the third position of Nägele.)

CASE XXXVI.—“No. 126. This woman was fifty-nine hours in labour; it was her first child. The pains were for a considerable time very trifling, with long intervals; however, for the last twenty-four hours the uterus acted with tolerable regularity, the pains being at times strong, causing the head to press with much force against the ischia, where it remained stationary for the greater part of that time. Her pulse was very much increased in frequency, varying between 120 and 130; the external parts were œdematous. As the foetal heart had ceased to act, having been distinctly audible in the right iliac region six hours before, the head was lessened, and the crotchet applied. The placenta was expelled in forty-five minutes, immediately after which, in consequence of hæmorrhage, the hand was introduced, and so it was arrested. Violent inflammation and sloughing set in, resisting all treatment, and she died on the 9th day. For four days previous she had severe diarrhœa, a succession of motions coming on suddenly, with severe pain; she had also severe hiccough. On examination after death, the vagina was found in a state of slough; the sides opposite the spines of the ischia were broken through with the slightest force, and were completely gangrenous. A circular opening the size of a shilling was found, forming a communication between this cavity and the rectum, the mucous

surface of which, as also that of the colon, was softened, and had, in the vicinity of the opening, a gangrenous appearance. There was no symptom of inflammation in the peritoneum or uterus.”*

CASE XXXVII.—“No. 1091. Was admitted August 23rd, in labour of her first child, and was not delivered until the 25th, being a period of fifty-six hours. Uterine action from the commencement until within six hours of the expulsion of the child, was extremely feeble, with long intervals. The head remained high in the pelvis, and although the ear could not be reached, it was evident the head had sufficient room to pass; to effect which, uterine action was alone wanting. As soon as the pains began to be brisk the labour proceeded without difficulty. The foetal heart was quite audible until eight hours previous to the birth. In three hours after the hand was passed to remove the placenta, it was found separated, and without the slightest effort the uterus contracted and expelled both. The perineum had suffered considerably in the passage of the head. The patient never seemed to rally after delivery; the pulse continued quick; there was considerable tenderness on pressure over the uterus, with a foul discharge from the vagina. * * * On the 7th and 8th she had distinct rigors, followed by perspiration, after which her strength became greatly reduced. The vaginal discharges continued foul, notwithstanding the most rigid attention to cleanliness and the use of stimulating injections. She gradually sank and died on the 11th day, having for two days previous suffered from frequent hiccough. On dissection, the only morbid appearances found, were in the bladder and vagina. In the bladder, the mucous surface was covered with yellow lymph, and it contained a quantity of muco-purulent fluid. In the vagina, opposite the right ischium, a portion appeared to have been destroyed by slough.”†

Hitherto, under the present section, I have spoken of the dangers which the mother may avoid by employing the operation of turning as a substitute for instrumental delivery, in cases of contraction of the pelvic brim. But while turning enables us, as I have shown, to eschew some of the gravest and most imminent dangers connected with the use of the long forceps and crotchet, it is on the other hand, by no means to be forgotten, that it subjects the mother to one great form of danger, from which, in common belief, she would be comparatively free under the adoption of instrumental delivery. The special maternal danger attending upon turning is *laceration or rupture of the uterus*, confessedly the most fatal complication that can occur in connection with delivery. Is the liability to rupture under turning so great as to make us avoid this practice and trust rather to the forceps and crotchet? Or, in other words,—

Is Rupture of the Uterus in Contracted Pelvis, much more apt to be produced by Delivery by Turning than by Delivery with Instruments?

Most authors describe laceration of the uterus as

* Practical Treatise, p. 158.

† Practical Treatise, p. 483.

one of the principal hazards which the mother runs in cases of turning. But injury and laceration of the uterus are perhaps not so liable to follow this operation as is generally imagined. "Between the years 1823 and 1834, (says Dr. Ramsbotham,) I delivered more than one hundred and twenty women under transverse presentations; independently of a few cases to which I was summoned where spontaneous evolution occurred. Many of these cases presented a formidable appearance; for in one the membranes had been ruptured a whole week; in another, sixty-nine hours; in a third, fifty-eight hours; in another fifty-five; in another, fifty-three; and in many, more than forty-eight; and as a general principle, we presume that the longer the liquor amnii has been evacuated, the more likely is the uterus to have embraced the foetal body firmly, and the more difficulty will there be in overcoming the resistance. In none of these cases did I exhibit large doses of opium, and in those few where bleeding was practised, that operation was had recourse to, not for the purpose of relaxing the uterine fibres, but to relieve the inflammation which the soft structures were suffering, and to remove tumefaction. *In not one of these instances was any injury inflicted on the uterine structure; nor did any permanent evil arise that could be attributed to the operation.* In four cases only was the uterus so powerfully contracted as to refuse admittance to the hand, and compel me to adopt the alternative of exviscerating or decapitating the fœtus."*

Besides, that injury of the uterus is thus not so apt, as is perhaps generally imagined, to follow upon turning when carefully and cautiously performed, there are other considerations, which are calculated strongly to shew that the danger of laceration in the cases of pelvic contraction, most fitted for the practice we suggest, is not much, if at all, increased by the proposed operation. I shall state the considerations to which I shall refer.

In the *first* place, I would premise this important remark, that (according to all our best obstetric pathologists,) those degrees and forms of morbid contraction of the brim of the pelvis which I deem to be the cases best adapted for delivery by turning, are exactly those cases on which, under any plan of management, (whether the patient be delivered by the natural efforts, or by the forceps or crotchet,) rupture and laceration are exceedingly apt to take place. On this subject I am anxious to adduce full evidence, and will consequently appeal to the unprejudiced testimony of Ramsbotham, Denman, Churchill, &c.

"Laceration of the uterus (says Dr. Ramsbotham,) is most likely to happen to a patient who has had three or four children, who possesses a slightly distorted pelvis, and who has been in strong labour for a number of hours. Although (he further observes,) the same rent may take place in any portion of the organ,

its most frequent seat is at the neck, either at the posterior part opposite the prominence of the sacrum, or anteriorly, behind the symphysis pubis. The direction is also mostly transverse, or slightly oblique. It is not difficult to account for this being the most usual situation of the injury; for since, during the latter part of gestation, the neck of the womb rests upon the pelvic brim, if the promontory of the sacrum dip too far forward, or the ridge of the pubes be preternaturally sharp, it is reasonable to suppose that the uterine structure may be affected, that inflammation may occur as a consequence of pressure, and that a thinning or softening of the substance may be induced, and, under these circumstances, should the structure give way at all, it is likely that the weakened part will be the first to suffer. Denman, indeed, says that, independently of disease, the uterus may be *worn through* mechanically, in *long* and *severe* labours, by pressure and *attrition* between the head of the child and the projecting bones of a distorted pelvis, especially if they be drawn into points, or a sharp edge. One or other of these causes may explain (Dr. Ramsbotham concludes,) why we more frequently meet with laceration of the uterus, when the pelvis is *slightly* contracted in the conjugate diameter of the brim, than when the distortion is *excessive*."* And he adds one case. "In one of the last cases" says he "of ruptured uterus to which I was called, dissection shewed that the linea ileo-pectinea, where it traverses the pubes, was formed into a very sharp ridge, that there were a number of bony prominences jutting from the inner surface of the pubic bones towards the cavity, and one, especially, situated above the left thyroid foramen, which was so pointed as to pain the finger when hard pressure was made on it. The sacro-pubic diameter was two inches and three quarters in extent. It was the woman's second pregnancy; the first child had been delivered by craniotomy. After a consultation held, labour on this occasion was induced in the eighth month by the exhibition of four doses of the ergot. The membranes broke spontaneously three hours and a half before the accident occurred. I was sent for by the gentleman in attendance, immediately, and delivered by turning; she died on the night of the fourth day."†

Dr. Churchill expresses similar views in regard to contraction of the pelvis as a cause of rupture. "A certain amount," says he, "of narrowing of the upper outlet, may give rise to it. This is a purely mechanical cause. The head of the child is forced down by violent labour-pains, but is unable to enter the pelvis, from the contraction of the upper strait. Now, if the pains continue with great power, the head is turned to one side or the other, or posteriorly, and the only obstacle here being the uterine or

* Obstetric Medicine and Surgery, p. 469.

† Principles of Obstetric Medicine and Surgery, p. 469.

vaginal parietes, the head is drawn through them at the weakest part. They offer the less resistance, probably from the woman having borne several children.*

Other authorities might be adduced to the same effect,—viz., that rupture of the uterus is especially liable to happen under protracted labour or instrumental delivery, when the brim of the pelvis is slightly contracted,—that is, in exactly the class of cases most likely to be adapted for delivery by turning.†

In the second place let me observe that, while contraction of the pelvic brim is thus acknowledged to be a strong predisposing and exciting cause of rupture, it must, at the same time, be held in view as a most important correlative fact, that it seldom does lead to laceration of the uterus, unless the effects of its mischievous agency are allowed to be combined with, and increased by, a morbid degree of prolongation and protraction of the labour itself. Dr. Denman's observation is, doubtlessly, so far, quite true, as to the possibility that the "uterus may be worn through mechanically, in long and severe labours, by pressure and attrition between the head of the child and the projecting bones of a distorted pelvis, especially if they be drawn into points, or a sharp edge."‡ In fact the liability to rupture, like the liability to most other obstetric complications, increases progressively with the increased duration of the labour, as the following table, calculated from Dr. Collins' returns,§ sufficiently attests:—

TABLE XV.

Duration of Labour in 24 Cases of Rupture of the Uterus.

<i>Length of Labour.</i>	<i>Number of Deliveries.</i>	<i>Number of Cases of Rupture.</i>	<i>Proportion of Cases of Rupture.</i>
Within 6 hours	13,412	7	1 in 1,916
From 7 to 24 hours	2,174	10	1 in 217
Above 24 hours	264	7	1 in 38

The principle inculcated by the evidence of this table is so important in its bearing upon the practice suggested in the present memoir, that I shall take an opportunity of enforcing it by adducing three instances of distorted pelvis, in which laceration of the uterus took place after the labour had been allowed to become

protracted; and that, though the mode of ultimate delivery in each of the three was different,—in the first being effected spontaneously, in the second by instruments, and in the third by turning.

CASE XXXVIII.—"No. 22. On the fifth day after delivery, without any apparent cause, was seized with violent hæmorrhage. When we saw her, which was immediately after, no pulse could be felt, and, though most prompt and active measures were employed, she died in less than an hour. She had been delivered, by the natural efforts, of a living child, after a labour, not very severe, of forty-eight hours; nor from that time was there distress of any kind perceptible.

On dissection, the abdominal viscera appeared healthy, as did the uterus, at first sight, but on raising it out of the pelvis, about the size of a shilling of its muscular substance, corresponding to the projection of the sacrum, was found to have given way, the peritoneal covering remaining uninjured. There were two spots in the vagina approaching to a state of slough."||

CASE XXXIX.—"No. 28. The labour pains in this case were feeble, yet the child continued to advance. The heart's action was audible with the aid of the stethoscope, the mother's pulse natural, and no unpleasant symptom. Suddenly, however, the most alarming debility came on, the pulse being scarcely perceptible, accompanied with vomiting and much pain on pressure over the uterine region. Immediate delivery was necessary, and the perforator was used. She was a feeble delicate woman, was thirty-six hours in labour previous to the setting in of the above symptoms, and had been force-delivered eleven months ago. She died in fourteen hours.

"On dissection, an opening was found at the junction of the uterus with the vagina, (exactly opposite a projection of the last lumbar vertebra,) not larger than to admit the passage of one finger. The muscular substance of the uterus, anteriorly, had also given way to a considerable extent, the peritoneum being whole. The pelvis scarcely measured three and a half inches from pubes to sacrum."¶

CASE XL.—"A patient with her spine somewhat curved, and who, in her first confinement, had borne a dead infant, after several days suffering, was taken in labour of her second child, early on the 16th November, 1846. The pains had been constant and strong for about thirty hours, when I saw her, with Dr. Gordon, who had been called in, and the head had remained stationary and fixed at the same point of the brim for the last twenty-four hours. On examination, Dr. Gordon and I found the pelvis small, the os uteri

noted as existing in sixty cases. Drs. McClintock and Hardy, in their excellent work on "Midwifery," observe, in regard to the pathology of rupture, (p. 295,) that the accident is more likely to be produced "where the deformity of the pelvis is slight, than where it is excessive,"—that is, in precisely those cases best fitted for turning.

‡ Ramsbotham's Principles of Obstetric Medicine and Surgery, p. 469.

§ Dr. Collins met with 34 cases of rupture during his Mastership. In 24 out of the 34 he has given the duration of the labours in a table in his "Treatise," p. 307.

|| Dr. Collins' Practical Treatise, p. 287.

¶ Dr. Collins' Practical Treatise, p. 300.

* Theory and Practice of Midwifery, p. 408.

† See, for example, Dr. Robertson, (Edinburgh Med. and Surg. Journal, Vol. xlii., p. 61.) "In a great majority of instances (says he,) of slight contraction of the inlet, in perhaps three cases out of four, the diminution of space is caused by the promontory of the sacrum encroaching upon the antero-posterior diameter. On this ground, perhaps, we may explain why, in a somewhat greater number of cases of laceration, the rent is found in the posterior, rather than the anterior, part of the uterus."

‡ Out of 300 cases of rupture of the uterus, reported by Dr. Trask, ("Monthly Journal and Retrospect" for August, p. 178,) contraction of the brim of the pelvis was found

fully dilated, and the head of the infant imperfectly entered into the brim, and apparently uninfluenced in its descent by the powerful uterine contractions that were present. The sutures of the foetal head were strongly overlapping, and a triangular portion of the foetal cranium terminating in the posterior fontanelle was driven deeply in and below the level of the two other portions of bone that went to the formation of that fontanelle. On first touching the head I thought this indented bone was, as usual, the occipital, but a more careful examination showed me that it was the left parietal bone, and that the head presented its right side, instead of the vertex. The head, though thus greatly compressed transversely, still filled very imperfectly the pelvic brim, and the right side of the pelvis was so unoccupied as to allow a long loop of the umbilical cord to prolapse. The vessels of the cord were beating, shewing the child to be still living. The local and constitutional symptoms under which the patient was suffering shewed the necessity of immediate interference and delivery; but how was the delivery to be accomplished? The mass of the head was too high above the brim to allow of the successful use of the long forceps, even if there were space sufficient (which was very doubtful,) in the contracted pelvis to allow of the head passing in this form. The perforation and breaking up of the head by craniotomy would allow of delivery, but the cord showed the child to be alive, and I had doubts here, as in other cases, of the propriety of murdering the infant, when delivery by other means was possible; the other remaining means consisted in its extraction by turning, and, with Dr. Gordon's consent, I proceeded to deliver the patient by this operation; it was accomplished without much difficulty. The child was still-born, but was recovered by the usual means of resuscitation; it survived, however, only a few hours. That part of the scalp covering the parietal bone, which had infringed so long on the promontory of the sacrum, remained depressed, and pitted like an umbilical mark; the left parietal bone itself remained also deeply displaced, and indented below the corresponding edges of the occipital and right parietal, and on dissection some blood was found effused beneath it. The mother continued well for a few hours, but then began to sink with symptoms of abdominal effusion and rupture. She died on the following day. On dissection, the neck and lower part of the body of the uterus were found lacerated, and at one part the oblique and valvular-like laceration extended through the peritoneum. The pelvic brim was obliquely ovate in form, the right side being much larger than the left, but the conjugate diameter of the brim was very narrow. At its most contracted point a piece of wood wedged in between the promontory of the sacrum and the nearest point of the pubis, measured only two inches and seven-eighths. The pelvic joints felt loose and mobile.

The observations which I have adduced in the preceding pages seem then to point to the following deductions:—

First. Morbid contraction of the pelvic brim is whatever mode of delivery is adopted, liable to be a cause of rupture of the uterus.

Secondly. This morbid contraction principally and

almost only becomes a cause of rupture, when in conjunction with it, the labour, as in the three cases just now detailed, has been allowed to become long and protracted in its duration, and the compressed tissues of the cervix are consequently rendered preternaturally friable and lacerable. Then,

Thirdly. It necessarily follows, that this complication would in all probability be avoided, (when morbid contraction of the pelvis exists,) provided either nature or art was enabled to deliver the patient early, and did not permit of the tissues of the lower part of the uterus becoming wedged in, contused, inflamed and softened, between the presenting head of the infant and the opposing points of contraction in the pelvic brim. Hence a power of artificially terminating labours with this complication as soon after their commencement as the dilatation or dilatability of the passages would allow, would be, so far, a means of averting this fearful accident under these circumstances. In the delivery by the operation of turning, we possess such a power; and by the exercise of it in these cases we may, I believe, not only sometimes save the mother from danger, but the child also from death. And I have already shewn at sufficient length, that the degree of force required to extract the head, will depress and groove the cranial bones of the child without necessarily injuring or tearing the soft pelvic tissues of the mother; provided always these tissues have not been previously brought into a state of congestive and inflammatory friability by the previous duration of the labour, and by the impaction of the head having been allowed to be prolonged to an excessive and morbid degree. All the evidence which I have adduced in different parts of the present memoir, goes to shew this fact,—that the danger attendant upon turning and other modes of operative delivery is, as a general law, regulated less by the mere performance of the operation, than by the mere degree of protraction allowed to elapse before operative interference is adopted. And, in addition, the evidence which was brought forward in the last section appears to entitle us to deduce as a supplement or corollary to this important general law, that, (supposing the maternal passages are once dilated or dilatable,) when operative delivery by the forceps, or crotchet, or turning, is accomplished with *comparative force*, it is safer, *cæteris paribus*, to the mother when performed early, than the same or other modes of operative delivery would be if accomplished with *comparative facility*, but performed late;—that, in other words, force is less dangerous than protraction;—that the hazards of operative delivery are more regulated by the time of its adoption than by the difficulties of its accomplishment.

Fourthly. It must still be held constantly and prominently in view that, in the proposed practice of turning, the great maternal danger which the practitioner has to avoid, is injury and laceration of the uterus, and he

must use all due care and caution to avert any chance of this accident. The preceding observations shew some of the leading points and objects which he should attend to, in order to avoid it. These points are, principally,—1, the early performance of the operation; 2, when possible, (as in Case I.) it should be effected even before the membranes rupture, as turning is greatly more easy and more safe before than after the evacuation of the liquor amnii; 3, if the liquor amnii has escaped, and the uterus has contracted, the uterine fibres should be previously and perfectly relaxed by the use of opium or chloroform; and, 4, the part of the operation consisting in the actual turning and version of the child, should be done with extreme caution, and only and always attempted and accomplished during a perfect interval between two uterine contractions.

Other requisite rules and precautions are enumerated so fully in most obstetric works, and so well known to obstetric practitioners, that it is perhaps unnecessary to dwell here at greater length upon them.

(To be continued.)

Hospital Reports.

CUMBERLAND INFIRMARY, CARLISLE.

SURGICAL CASES UNDER THE CARE OF W. B. PAGE, ESQ., SURGEON TO THE INFIRMARY.

(Communicated by E. THOMAS, Esq., House-Surgeon.)

FOOT TORN OFF, AND WITH IT THE FIBULA, AND MOST OF THE MUSCLES OF THE LEG; RESISTING POWER OF THE VARIOUS PARTS; AMPUTATION OF THIGH; PHLEBITIS: POST-MORTEM APPEARANCES.

John S., aged 40, a pilot, was admitted into the Cumberland Infirmary, under the care of Mr. Page, about midnight, November 5th, 1848.

Five hours before his admission, while engaged at the stern of a steam-vessel, letting out a rope which had become in some way connected with another vessel which was passing, his right foot became entangled in a coil of the rope, and in an instant, (his body being firmly fixed by the bulwarks,) his leg was dragged off with such violence as to be carried near the bows of the vessel. A cart having been procured he was placed in it and brought to the infirmary, a distance of twelve miles. When admitted, he was blanched, cold, and prostrate, the quantity of blood which he had lost on the road was great, and the amount of hæmorrhage on board the vessel was stated to have been very considerable. His only complaint was of excessive pain in the lower part of the back, where no trace of injury was apparent. He was at once put into a warm bed, and heaters were applied to the sound foot, the back, and abdomen, oozing of blood continuing to take place. In about an hour after his admission,

Mr. Page removed the limb, four inches above the knee by the double flap operation.

The state of the limb was as follows:—The skin of the leg was uninjured, and hanging loosely down around the tibia, which was entire, presenting somewhat the appearance of a trowser around a wooden leg; behind the bone, and nearly of equal length with it, hung the post-tibial nerve. The tibia was quite bare on its anterior surface, and posteriorly and externally to within four or five inches of the knee. The two heads of the gastrocnemius retained their bony attachments, the lower end of that muscle was much lacerated where it had become detached from the tendo Achillis. The foot was still in the boot, a sort of highlow, the skin was ruggedly torn around the ankle, and attached to the foot was the fibula and most of the muscles of the leg. The fibula was separated from the tibia at its superior articulation, and was fractured about an inch above the ankle; in front was the tendon of the tibialis anticus, having connected with it the greater part of the belly of that muscle, and the tendons of the extensor pollicis proprius, and extensor longus digitorum. Behind, was the tendo Achillis, with the whole of the soleus and a small part of the gastrocnemius, and the tendon of the plantaris, with the belly of that muscle attached. The tendons of the flexor digitorum longus, of the tibialis posticus, and of the flexor pollicis longus, as also that of the peroneus longus had connected with them the whole of their respective muscles; those of the peronei brevis and tertius had no muscular fibre attached.

Although almost pulseless while on the table, he revived somewhat shortly after his return to bed, and as he continued to complain much of the lumbar pain, a drachm of laudanum was given him. During the night he had some sleep; throughout the day he took as much nourishment as was desired, and gradually rallied. The pain in the lower part of the back was a frequent cause of complaint, and was considered to be dependent upon the tension and laceration to which the great sacral nerves had been subjected.

November 5th. Slept tolerably through the night, without opium; occasionally disturbed by startings in the stump; complains much of his back; takes his food well.

6th. Appears going on well.

7th. Had scarcely any sleep through the night; still complains much of the back, but not at all of the limb. Stump dressed; it has a doughy unhealthy appearance; discharge thin and fetid. Water-dressing applied. Liquor Opii, forty drops at bed-time.

8th. Had a good night; stump more swollen; cutaneous veins much congested; has great difficulty in swallowing and speaking, from a circumscribed swelling beneath the chin, and bulging into the mouth on either side of the frænum linguæ. Has much pain in the second joint of left thumb, extending up the arm; had a shivering fit; tongue dry; wanders a little; pulse very frequent; breathing short and hurried; extremely anxious and irritable. Opiate at bed-time.

9th. Had a very restless night; joint of thumb red, swollen, and painful. Has much pain in both arms, so that he cannot bear them to be moved. Stump more

swollen, and veins more distended; discharge fœtid, and mixed with flakes of lymph. Is evidently sinking.

10th. Three, a.m., died.

Autopsy eighteen hours after death. The stump only could be examined. The integuments from the front of the thigh being reflected back upon the abdomen, the cutaneous veins, including the saphena, were found much congested; their serous lining appeared healthy. The femoral artery and vein were next exposed; the ligature from the former had separated, and a plug of coagulum occupied its extremity. The vessel was healthy. The femoral vein, when laid open throughout, was found filled with pus and partially liquified fibrin; its lining membrane had lost its smooth shining surface, and had become dull and villous. The glands over the saphenous opening were enlarged, and some of them contained pus. The hip-joint was healthy, and there were no purulent deposits in the muscles of the thigh. The areolar tissue surrounding the sciatic nerve, throughout its whole extent, was found infiltrated with coagulated blood.

VARICOSE ULCER; LIGATURE OF VARICOSE VEINS;
PHLEBITIS; DEATH: POST-MORTEM APPEARANCES.

James B., aged 54, a weaver, was admitted into the Cumberland Infirmary under the care of Mr. Page, September 27th, 1848, with ulcer of the left leg, of very long standing, and a general varicose state of the veins of that limb.

October 2nd. The twisted suture was applied to the trunk of the internal saphena, and to two other superficial veins below the knee, the needle being in each case passed behind the vein. The limb was lightly bandaged, and the patient kept at rest.

9th. No untoward symptom arose until last evening, when he was attacked with violent palpitation, but, inasmuch as he had laboured under a similar affection before, he considered it of little importance. A dose of tincture of digitalis was given, from which much relief resulted. At one this morning he was suddenly attacked with shivering, which was followed by a return of the palpitation. He now for the first time complained of some tenderness in the groin, where the glands were found somewhat enlarged. The skin immediately surrounding each of the sutures, appeared unduly inflamed, but there was little if any swelling, either of the limb generally, or in the course of the cutaneous veins. The needles were removed, and the limb enveloped in cotton-wool. Throughout the day the tumultuous action of the heart continued, with a feeble, very frequent pulse. He had occasional rigors, and was drenched in perspiration. The typhoid symptoms gradually increased, and towards night he became delirious.

During the following day he continued in a partially unconscious state, but complained slightly when examination was made of the limb, which was now rather swollen. The glands in both groins were found enlarged. All the symptoms of the previous day continued, and his vital powers were rapidly diminishing.

11th. Died about noon.

Autopsy ten hours after death.—The integuments were carefully dissected from the left thigh and leg, and the superficial veins exposed. The internal saphena vein, from

the part on which the suture had been placed, up to its junction with the femoral, was found to be much larger than usual, and of a dull red colour throughout, the redness somewhat abruptly terminating at its upper extremity; it was filled with a fibrinous clot, firmly adhering to the coats of the vessel. The two other veins on which the ligature had been placed were filled with tenacious coagula, but presented no abnormal appearance; the needles had in each case produced ulceration through the entire calibre of the veins, and in these situations were small collections of healthy-looking pus. The femoral vein, which was very large, was filled with firm coagulum; the glands in both groins were much enlarged and on the left side contained pus; the right knee-joint was swollen, and contained several ounces of purulent fluid; no purulent deposits were found in any of the internal organs, or elsewhere, but the circumstances under which the investigation was made, precluded any very minute examination. The structure of the heart was healthy; the pericardium contained several ounces of serous fluid, in which were some flakes of lymph. All the venous trunks which were laid open were filled with firm coagula.

Phlebitis occurred in two other cases in this hospital, at a period intermediate between the foregoing: in the one after excision of the os calcis, in the other after the removal of a sequestrum from the femur. In these cases the disease was circumscribed, and did not cause a fatal termination by the contamination of the general circulating fluid with the morbid products of the inflamed vessel.

The series forms an interesting exemplification of the "epidemic constitution," on which the occurrence of this disease so often depends, for that four cases should have arisen in so short a period, and in a hospital which, during the seven years since its establishment, has presented no other case, can only be supposed to have been dependent upon "some predisposition of the human body, engendered by the operation of influences, which are, probably, atmospheric." Erysipelas, in a severe form, was coincident with the phlebitis in the hospital,—diseases in every way identical in type, and without doubt very generally identical as to the causes on which they depend.

PROVINCIAL *Medical & Surgical Journal.*

WEDNESDAY, JANUARY 10, 1849.

It is essentially requisite, for the purposes of good government, that those intrusted with power, of whatever description, should be men of character and integrity of purpose; should be possessed of habits of business and industry, and thoroughly acquainted with the nature and details of the subjects intrusted to their management. No one who is deficient in any one of these qualifications is fitted for employment in the public service. A man may be possessed

of a high character for integrity and of business-like habits, but if he is unacquainted with the nature of the responsibilities which he undertakes, his energy will only lead to a mischievous and misplaced activity, and his integrity cannot but be exposed to continued injury.

To refer for an instance at which no offence can be taken,—who in this day will question that the Duke of Wellington is eminently possessed of these high qualifications? and his talents being devoted to a profession in which he has shewn all the power of a master-mind, have achieved for him a reputation and general esteem which it falls to the lot of few to attain. Now let us suppose that a former government, instead of confiding the control of the Military Department to such a man, had thought fit to reward his services, at the close of the Continental war, by placing the office of Lord Chancellor in commission, and appointing him as the head of the Board, while at the same time they selected a member of the Bench of Bishops, equally eminent, perhaps, for theological learning and piety, and as a lover of peace, as Commander-in-Chief of the Army, could any one fail to see the absurdity of such a misapplication of the principles which ought to regulate the selecting for the public service of persons fully acquainted with the duties required of them. And yet, to descend to affairs of less moment (we were about to say,) than the administration of justice, and the regulation of military affairs, or rather, to take up a still higher position,—that which concerns the lives, the health, the comforts, and general welfare of the community at large, we see in these days, and by the government which now is, the care of the public health, and the control over all which concerns it, intrusted to men eminent, perhaps, for character and talent, and habits of business, but entirely unqualified by (to them,) an insurmountable want of knowledge of everything connected with health and disease. We may even go farther, and say, that the present Chairman of the Board of Health, amiable and respectable as he is as an individual, is absolutely disqualified for the office he now holds—that he is, perhaps, one of the last men in the kingdom who should have been selected for the office, as his known perversion with regard to one of the fashionable quackeries of the day renders him as unfitted for participating in anything which concerns the management of the public health, as would be

an avowed infidel for presiding over the destinies of the church, or a member of the Society of Friends for taking the command of the army in the Punjab.

We have a great respect for the higher classes of the legal profession, we believe them to be, for the most part, highly qualified by long practice and the nature of their studies and pursuits, for the investigation of all matters of evidence, and we have no objection to see gentlemen of this profession appointed to assist at the deliberations of a Sanitary Commission, or a Board of Health. On the contrary, we believe that the several departments of the public service are of so complex a nature, as to require the admixture of men of different professions in the Boards of Management; but then the nature of the department should, in all cases, lead to the selection of the individuals composing these Boards. For instance, the public service would be materially benefitted by having an army or navy physician or surgeon of eminence attached to Military and Naval Boards of various descriptions, to consult with, and advise upon, all matters connected with the health and efficiency of the soldier or sailor,—such as the selection of places of salubrity for military posts, the general care of the men, the proper adaptation of clothing, diet, &c., to the nature of the services to be performed. But, to compose a military board mainly of medical officers, with perhaps a nobleman, unacquainted with, or an amateur meddler in, military matters, as its chief, and one general officer to give advice upon such military measures as may be proposed, would be supreme folly; yet is this *mutatis mutandis* the constitution of the present Board of Health. Again, were all doubtful questions connected with the higher points of the law, instead of being submitted, as at present, to the decision of the assembled judges, to be determined upon by a board or commission, consisting of dignitaries of the church, military officers, eminent physicians, in short of anything rather than those by profession learned in the law, and presided over perhaps by some man notorious for his disregard of all law, would it be one whit more absurd than is the constitution of the present Board of Health?

Who are the members of the present Board of Health? Let them be tried by the standard we have endeavoured to lay down. 1. An avowed supporter of mesmerism as president. 2. A most zealous and benevolent nobleman, to whom

the duties of chief of the Poor-Law Commission might have been well committed, but guiltless, as far as we know, of any pretensions to medical knowledge. 3. A barrister, well-fitted perhaps by his investigations of sanitary questions for a seat at a Sanitary Board, but having no practical acquaintance of disease and its causes. And, 4, as a kind of appendage, last in rank, and evidently least in estimation, (by the Government authorities we mean,) a physician, with a temporary and subordinate appointment as *the* medical member of the Board, held we presume during good behaviour, or perhaps during the term of such compliance with the wishes of the other members of the Board, as may afford to them the sanction of his name and authority as a physician, and to himself the personal responsibility of the many ill-judged measures which a Board so constituted cannot but perpetrate.

A Board of Health, such as the present exigency requires, should have been formed mainly of men well acquainted with medical science and practice, and with the investigation of medical questions, presided over by some nobleman or gentleman connected with the Government to give the requisite Government authority, and aided, perhaps, but certainly not directed, by some such man as Mr. Chadwick. The cholera has now been about three months in this country and hitherto has happily made but little progress. In this we cannot but recognise the hand of an all merciful Providence arresting the Angel of Pestilence; and we trust that the interval thus allowed may be spent by those amongst us who have means, in providing those comforts of food, warmth, and clothing, to the poor and necessitous, which the present season especially requires, and in so raising their general sanitary condition as may render the whole population, humanly speaking, less amenable to the attack of this destructive pestilence. But should the cholera ultimately break out with any degree of severity, and extend its ravages, whether in the metropolis or the country, fearful will be the responsibilities which the noble head and the other unqualified members of the Board of Health has taken upon themselves. Vacillating and contradictory as have been their previous measures,—their recommendations opposed to the highest medical authorities in the country, and already even productive of most mischievous effects,—without possessing one qualification to entitle them to

the confidence of the public, and their lengthy manifestos treated with deserved neglect by the members of the medical profession, who alone are the fitting judges of the real value of any measures what may be proposed by them,—what must be the self-reproaches of these unfortunates, should the disease appear in all its intensity amongst us, no effectual provision taken against it, none for the medical superintendence of the health of the country generally, none for medical attendance on those who may be attacked, save under the control of the unqualified local boards of a non-medical Commission, and by the already over-tasked Medical Officers of the Unions? How can the result, when the period anticipated arrives, be otherwise than overwhelming hurry and confusion, and most pitiable indecision at head quarters, and an uncertainty and alarm to the public generally, which the instant and vigorous adoption of some systematic measures, by a Board of Health properly qualified and entitled to public confidence alone can avert?

We put it to Lord Carlisle and his colleagues, seriously and conscientiously to consider whether they are fitted for such an emergency, and, as men of honour and principle, at once to resign appointments uncongenial to their habits of life, and for which they are manifestly unqualified; and at the same time, to recommend to her Majesty the formation of an efficient Board of Health, chiefly composed of men who are, by education, profession, and sufficient experience, really capable of discharging its duties with advantage to the public.

Review.

Observations upon Bulam, Vomito-Negro, or Yellow Fever, with a Review of "A Report upon the Diseases of the African Coast, by Sir William Burnett and Dr. Bryson," proving its highly Contagious Powers. By SIR WILLIAM PYM, K.C.H., Inspector General of Army Hospitals, and Superintendent General of Quarantine. London: 1848. 8vo, pp. 311.

The Cholera of Malta in 1837; from the Italian of Giuseppe Stilon, M.D., &c., &c., Physician to the Cholera Hospital in Valetta. By SETH B. WATSON, D.M. of St. John's College, Oxford, &c. London: 1848. 12mo, pp. 178.

We have classed these two publications together, not for the purpose of giving any extended account of

either; nor with the view of entering upon a discussion on the subject of contagion, to which, in some respects, they both refer. Our intention is merely to commend the first of them to the notice of such of our readers as may feel interested therein, as containing some valuable remarks in the mode of tracing out the existence of contagion with respect to a disease in which it has long been a *questio vexata*; and to refer to the second of them for an admirable instance of the good effects of careful supervision in districts where the cholera is actually in existence, or an outbreak of it expected, and equally applicable, whatever view may be taken of its mode of communication.

Our readers are probably aware that cholera raged with great severity at Malta in the year 1837, nearly 4000 individuals falling a sacrifice to it out of a population of 100,000. In a village about a mile distant from, and in constant communication with, Valetta, six or seven of the better class of resident English and Maltese formed a voluntary committee for the purpose of adopting precautionary and remedial measures. A qualified physician, Dr. Arpa, was engaged, at a monthly salary. "A house was taken for him in the centre of the village," (we quote from a letter by Sir John Stoddart, then Chief Justice of Malta,) "properly supplied with medicines and utensils; at the door were fixed a night-bell and lamp, and near the latter a board, inscribed, 'Advice and medicine gratis at all hours, for the cholera.' But the principal and most material stipulation was, *that the doctor should walk through the village morning and evening, inquire into the state of health of every family, and if any premonitory symptom appeared, should immediately apply to it the proper remedy.* With regard to the poor, the committee determined to relieve them, by giving, not soup, but bread, with a proportionate quantity of any kind of food to which they were most accustomed; only taking care that it should be digestible, wholesome, and sufficient; and Dr. Arpa kindly undertook to superintend the distribution every morning."

After these and other appropriate precautions, the result was, that while cholera was carrying off its hundreds in Valetta, and severely visiting all the neighbourhood, the mortality being nearly 50 per cent. of those attacked, at Sliema, the village referred to, there were only two deaths out of a population of 450, though there were at least forty cases arrested in the early stages, every one of which might, and probably would, have run into collapse, but for the constant medical surveillance adopted.

Proceedings of Societies.

SHEFFIELD MEDICAL SOCIETY.

Eighth Session.—First Meeting, October 5th, 1848.

Mr. RAY in the Chair.

Dr. Bartolomé was elected President; Messrs. Law and Skinner were re-elected Secretaries.

Second Meeting, October 19th, 1848.

The PRESIDENT in the Chair.

Dr. Bartolomé, the President, read a case of poisoning by arsenic, presenting some peculiarities. [This case will be published in a future number.]

Mr. Hunter then detailed two cases of abdominal tumours. During the past summer he had had the opportunity of watching the progress of two morbid growths within the abdomen, and of examining them minutely after death. They were alike in structure, having a character not often described, not well understood, and were interesting on account of their peculiar position. The term *malignant* seems to be too loosely applied to such tumours, and they appear to approach more nearly to the strumous character, exhibiting small collections of tuberculous matter, or, perhaps, an ill-formed curdy pus.

TUMOUR OF THE LEFT KIDNEY.

The first was a renal tumour. Ellen H., aged 21, married, was first seen in May last. She was greatly emaciated. On examining the abdomen a very large hard solid tumour was found, inclining rather to the left side, where it was felt to be both harder and more superficial than elsewhere. She complained of severe pain of the whole abdomen, accompanied by a most distressing sensation of distension.

She stated that about six months before she had been kicked heavily on the left lumbar region by her husband, and that from that time she dated her illness and the growth of the tumour, but that she had never applied until this period for medical assistance. Her bowels had required aperient medicines; her appetite was good, and she had slept well, except occasionally, when she appeared to have suffered from slight but painful attacks of partial peritonitis. Urine natural, both in appearance and quantity, so as not to attract the attention. Catamenia regular. She was under treatment for several weeks, sinking daily. Iodine and mercury were exhibited without success. The case was diagnosed to be one of ovarian tumour, perhaps rare, from the large size of the solid tumour, and the absence of fluid. Dr. Elam, on being asked to look at the case, thought it proceeded from the kidney. She died in July, and on *post-mortem* inspection all the abdominal and pelvic viscera were found to be healthy, except the left kidney, which was exceedingly large, measuring about twelve inches by seven, and four inches in thickness. Very little of the form and structure remained. There was no pelvis nor excretory surface, and no trace of the normal tubular structure. The tumour had a tough leathery consistence, particularly externally, and contained many small cavities, filled with yellow granular matter, like tubercle or strumous pus. The second case was more interesting from its locality.

TUMOUR IN THE RIGHT ILIAC REGION.

William W., aged 35, a green-grocer's assistant, was seen September 15th. When first seen he was found sitting by the fire-side, his complexion slightly jaundiced, and his countenance bore the dejected air met with in abdominal disease. Abdomen swollen, and in the right and left iliac regions the swelling was more distinctly marked, and much harder, than elsewhere. The other parts of the abdomen were tympanitic, and tender on pressure; liver not enlarged. He stated that two years ago he had been kicked by a mule over the right iliac region, from which time he had never been free from uneasiness, and afterwards acute pain, in the part, nor had he been able to lie on the right side. The alvine evacuations had become irregular, and he had sent for medical assistance in consequence of his bowels not having been evacuated for ten days. He had no colic; no hernia. A dose of calomel and jalap was administered, followed by senna mixture, and two aperient pills at bed-time.

The next morning when seen, it was found that he had vomited all the medicine; bowels not open. A turpentine enema was administered, and five grains of calomel every three hours, with sulphate of magnesia, in the infusion of roses. The enema returned untinged. The calomel and salts remained. Abdomen in the same state. Full doses of croton oil were then administered, without producing any intestinal movement.

17th. Hiccough and vomiting had supervened; pulse full and firm; no evacuation of the bowels; abdomen more swollen and tender. The matter vomited was not of fecal character. He was freely bled, and with the advice of Dr. Elam the cold douche was applied, which produced temporary collapse. The pulse recovered itself, and a temporary spasmodic contraction of the abdominal muscles took place. Small doses of calomel were given, and several large injections of aloes and turpentine exhibited. Mercurial liniment had been freely rubbed over the abdomen.

18th and 19th. The abdomen was enormously swollen and painful, and in parts tympanitic. The hiccough and vomiting had so much increased as to preclude the administration of medicines by the mouth. Large injections and opiates were given, and, by way of experiment, a dose of metallic quicksilver, a remedy recommended by the late Dr. Younge, of Sheffield, was given. The vomited matters not stercoraceous.

On the evening of the 19th he sent an urgent message, begging to be relieved by operation, as he believed his case to be rupture. In consultation with Dr. Elam, Messrs. Parker and Micklethwait, it was determined, as there seemed to be no other prospect of saving him from death, to establish an artificial anus, according to Amusat's lumbar section, which does not interfere with the peritoneum, nor endanger any important vessels. In this case the cæcum appeared to be the highest seat of disease, and the right iliac region most distended. An incision about four inches in length was made through the skin obliquely across the anterior edge of the quadratus lumborum, and across the common tendon of the abdominal muscles; it was continued through muscular and fascial fibres, until the back of the cæcum was exposed. This

was not found to be so much distended as was expected, still it protruded from the wound, and was attached by two sutures on each side, to the lips of the wound, and was slit up. A quantity of feces escaped, but not so large a quantity as was anticipated. On examination, the small intestines were found to be so much distended, as to cause apprehension of obstruction higher up, and as a proof of obstruction lower down in the tube, a large injection did not find its way to the wound. Very little relief was afforded; occasionally a small quantity of feces passed by the wound, and a small globule of mercury was found in the dressings. Vomiting and hiccough continued until the 22nd, when death closed the scene.

On inspection, on the 23rd, a tuberculous mass was found attached to the inner surface of the abdominal parietes in the right iliac region, having a very strong leathery and blackened coat, containing yellow matter, most probably incomplete pus of a chronic abscess in a scrofulous subject. It was larger than a hen's egg, and fluctuated slightly. Small intestines enormously distended, and the lower part of the ileum entered into the tumour, and three inches below it emerged, presenting a natural appearance. The large intestines were of natural appearance; part of the transverse arch of the colon entered the tumour, and passed from it as the smaller intestine had done. The two portions of intestine passing through the tumour were found to be pervious, so that this may be regarded as a case of fatal obstruction of the intestine, arising entirely from external mechanical pressure, and had there been only one (the lower,) obstruction, it is probable that the operation would have been successful.

Foreign Department.

ABSTRACT OF THE PROCEEDINGS OF THE ACADEMIE DE MEDECINE, PARIS.

The sittings of the past month have been mainly occupied by the discussion on gun-shot wounds, but before we give the continuation of this important subject, it will be advisable briefly to notice the following communication, which has been recently presented:—

AMPUTATION.

M. Sedillot has produced a memoir "On the Means of Ensuring Success after Amputating." This is best accomplished according to the author, by abandoning the circular operation altogether, and by substituting the *single flap* operation, which consists in making one large flap, involving two thirds of the anterior circumference of the limb, and removing the posterior third by an incision at right angles to the bone. The large anterior flap then falls by its weight alone, over the wound, and is readily kept in situ without the intervention of dressings. The flap is united on each side by a single suture, and a central canal is made for the escape of the purulent or other secretions, by previously inserting a piece of lint upon the extremity of the bone, and allowing it to hang out below the line of union of the flap. This is removed as soon as there is no

longer any fluid to escape. The stump itself is left uncovered, so as to allow of fomentation, the application of cold, or syringing of the interior of the stump, as occasion may require. The merit of M. Sedillot's plan consists mainly in preventing the accumulation of foul secretions in the interior of the stump, from which the chief danger of amputations is known to arise.

GUN-SHOT WOUNDS.

M. Velpeau defended the old idea of "burning" in gun-shot wounds, not that the ball retained sufficient caloric actually to burn the parts, but because the contusion produced by its passage caused mortification, which to all intents and purposes resembled the eschar from a burn. As regards treatment, he does not consider that the employment of refrigerant applications is so useful as is represented. He likewise objects to general bleeding as a preliminary. He did not order blood-letting in a single recent instance, and yet has not lost one by excess of reaction. He is not an advocate for "debridements," except under particular circumstances. He agrees with M. Malgaigne as to the injurious consequences of confining the wounded to rigid diet; he believes that a judiciously nutritious diet tends to prevent unpleasant consequences. As to amputation, if it is deemed necessary, he considers that it should be performed at once; the main question, whether in a severe gun-shot wound we should endeavour to save the limb or amputate, he does not consider so easy of solution, unless there is great destruction of the bone, when he considers the attempt to save the limb more than useless. One of the reasons alleged in favour of amputation is, that we substitute a simple for a contused wound. M. Velpeau does not acknowledge the justice of this opinion. On the whole he tries to save as many limbs as possible. In June last he amputated only six times in twenty-six cases of fracture, in the remainder he tried to save the limb. Of these, two only have died, the eighteen are cured, or bid fair to get well. Of the amputated cases he lost one-third. "*The older I grow*," observed M. Velpeau, "*the less I amputate*."

M. Huguier, who followed M. Velpeau, commenced by an examination of the respective diameters of the openings of entry and exit of gun-shot. He distinguished three types of these wounds. 1. Those in which the two openings are of equal size, and it is impossible from them to predicate the direction whence the ball came. 2. Those in which the opening of the entry of the shot is larger than that at which it escapes, in consequence of having struck a hard body, as a bone. 3. Those in which the reverse is the case. He regards the depression of the edges of the wound of entry, and the extension of the outer wound, as not to depended on, as they can only be seen for a short time after the reception of the wound. Other characteristics of gun-shot wounds, as charring and ecchymosis of the tissues, are also occasionally wanting, so that in a medico-legal point of view it is sometimes impossible not only to tell the direction of the ball, but even to be positive as to the wound being caused by a gun-shot at all. M. Huguier then reviewed the effects of

gun-shots upon different tissues, as skin, muscle, bone, blood-vessels, &c. In regard to wounds of bone, he maintained that when a ball traverses a bone on one side, and the other portion is fractured by the shock, the fractured ends always become necrosed.

The next speakers were MM. Jobert and Begin. M. Jobert entered at some length upon all the most interesting questions connected with gun-shot wounds. He at one time entertained the common opinion respecting the wounds of entry and escape of the ball, that the former was smallest with depressed edges, and the latter had the edges everted; later experience has convinced him that though the two openings are rarely similar, they vary *ad infinitum*. Sometimes he has seen the wound of entry small and round,—that of exit large and irregular; sometimes he has seen this reversed, and again he has met with them both of the same size. M. Jobert condemns the immediate extraction of balls unless very superficial. The treatment of gun-shot wounds differs according to the time which has elapsed since their infliction. The first period is one of shock and collapse, then there is a period of reaction and inflammation, and, thirdly, one of suppuration; it is evident thus a different treatment is required for each. He regards "debridement" as useless and dangerous, excepting in certain cases, in which the whole limb becomes greatly tumefied, with intense pain and agitation. In these cases a few incisions of five or six inches in length through the skin and aponeurosis has given immediate relief. M. Jobert concluded with some observations on comminuted fractures and amputations; on the former point he states that he has not amputated as a matter of course. In fractures, with penetration of the elbow-joint, he has saved the limb, which has recovered with partial ankylosis. So also in comminuted fracture of the head of the humerus, unless there is great destruction of the soft parts, he has treated the case effectually by a vigorous antiphlogistic plan. Comminuted fractures of the thigh without great injury of the soft parts, have also been subjected to regular treatment; fracture, with opening of the knee-joint, has also been similarly managed. He has saved three out of six thus treated, while Bell defied any one to save one limb in a thousand. His plan of treatment is to bleed largely, to use cold cataplasms during the inflammatory period, and warm fomentations when suppuration has commenced. He never extracts the fragments, and does not meddle with the original wound. Long incisions are made at a distance from the wound when there is much distension. By this treatment, conjoined to proper instrumental aid, M. Jobert affirms that he has great success. If, however, the soft parts are greatly injured, or large vessels are wounded, or articulations largely opened, amputation is the only resource. But, amputation being decided upon, should it be primary or secondary? This important question the speaker now enters upon. After comparing the opinions of the supporters of both sides of the question, he expresses his own conviction that, when amputation is necessary, it ought to be performed immediately, but he does not by this term mean that amputation should

take place during the period of collapse or shock; he waits till reaction is established, and the great functions of the body have recovered their balance. All he is anxious about is, to operate before the period of inflammation ensues. Consecutive amputation is, in his opinion, almost always unsuccessful.

M. Begin, who next addressed the Assembly, commenced his speech as did the others, by an account of the aspect of the entering and exit wounds. These characters, which he considers to be such as are generally described, soon disappear, but are again evident after cicatrization, when the former will exhibit a concave round scar, the latter an elevated irregular one. This speaker did not agree with M. Jobert, in his admiration of John Hunter's work on "Gun-shot Wounds;" according to him the work is full of errors. He approves of "débridemens," whenever the tissues surrounding the traverse of the ball are engorged, and as it were strangulated, and appealed to his own experience in 1813, as proof of the advantages of the operation. He differed from M. Jobert in reference to the extraction of the ball and other irritating bodies, which he considers ought to be done whenever practicable. M. Begin thinks that fractures from fire-arms, in most cases, require immediate amputation. If an attempt to save the limb in these cases be contemplated, the splinters are to be removed, unless strongly adherent, otherwise a secondary amputation will often be necessary. His views respecting the question of amputation are shewn in the following *resumé*:—

1. The wounds which are made by fire-arms never unite by first intention, but on the contrary inflame and suppurate throughout their entire extent.
2. Whenever the track of the wound is covered by dense aponeurotic structures, the orifices should be dilated, so as to allow a ready exit to the discharges.
3. The balls, splinters, &c., should always be extracted when possible, so as to reduce the wound to as simple a condition as possible.
4. Gun-shot wounds, after being thus treated, should have the simplest possible dressing; water-dressings are the best.
5. Fractures should be reduced immediately, and the limb placed in appropriate apparatus.
6. When amputation or resection of the fractured ends of the bone is necessary, the operation should be done at once, unless the patient be in a state of collapse.
7. During the inflammatory stage of gun-shot wounds an antiphlogistic regimen is required, but as soon as suppuration is established, the patient requires nourishing diet, and tonic medicines.

ABSTRACT OF THE PROCEEDINGS OF THE ACADEMIE DES SCIENCES, PARIS.

The principal memoirs presented since our last report are—

1. By M. Parchappe, "On the Gradual Diminution of the Cerebral Mass in Persistent Insanity."
2. A memoir by M. Demarquay, "On the Anomalies of the Right Subclavian Artery, with Absence of the Recurrent Nerve." (See *Prov. Journ.*, 1848, p. 584.)
3. A paper by M. Bourguery, "On the Capillary System."—4. "On Confluent Small-pox," by M. Serres, neither of which are important.

POOR-LAW MEDICAL COMMITTEE.

SANITARY DUTIES RECENTLY IMPOSED ON POOR-LAW
MEDICAL OFFICERS.

(Copy.)

To the Honourable the Poor-Law Board.

The Memorial of the Chairman and Committee of the
Medical Officers of Unions in England and Wales

Sheweth,—

That your memorialists having been duly appointed a Committee at a Convention of Poor-Law Medical Officers, assembled at the Hanover Square Rooms, on the 27th October, 1847, for the purpose of seeking an amelioration of the present system of Poor-Law Medical Relief, respectfully beg to call the attention of your Honourable Board to the powers conferred by the "Act for the Prevention of Nuisances and Diseases," whereby your Honourable Board is authorised to require from the Medical Officers of Unions, the performance of various duties in reference to Sanitary Regulations, without awarding any remuneration for such onerous and important services.

Your memorialists beg to protest firmly, but respectfully, against the imposition of such duties,—

1st. Because the said duties are altogether foreign to the special duties of Union Surgeons as medical attendants on the sick poor, and are not named, nor even contemplated by the Honourable the Commissioners of Poor-Laws in their order defining the duties of the Medical Officers of Unions, and because they are entirely distinct from the functions assigned to the Medical Officers of Unions in their contracts with the Boards of Guardians.

2nd. Because, such sanitary duties not being embraced in the legal contracts, nor in the instructions of the Honourable the Poor-Law Board, under which the Union Surgeons entered into their engagements with the Boards of Guardians, the orders of your Honourable Board are a violation of the rights of Union Surgeons as private citizens, and are contrary to the spirit of the common law of the land.

3rd. Because it is unjust to require the Medical Officers of Unions to perform arduous and valuable services without remuneration, and because such orders are at the present time peculiarly obnoxious and oppressive, inasmuch as the Medical Officers of Unions have for a long time complained of the great inadequacy of the present payments for their ordinary services as the medical attendants of the sick poor.

Your memorialists therefore pray, that your Honourable Board will imperatively award such remuneration for sanitary services as shall be equitable and just.

Signed in behalf of the Committee,

THOMAS HODGKIN, M.D., Chairman.

CHARLES F. J. LORD, Hon. Sec.

Convention of Poor-Law Medical Officers,
4, Hanover Square, Dec. 9th, 1848.

Poor-Law Board,
Somerset House, 18th Dec., 1848.

Sir,—I am directed by the Poor-Law Board to acknowledge the receipt of a Memorial of the Chairman and the Committee of the Medical Officers of Poor-Law Unions, acting under the authority of a Convention of Poor-Law Medical Officers assembled on the 27th October last, in which Memorial, the attention of this Board is called to the powers conferred by the 11th and 12th Vict., cap. 123, in requiring from the Medical

Officers of Unions the performance of various duties, having in view the removal of nuisances and the prevention of contagious and epidemic diseases; and a protest against the imposition of such duties is conveyed therein for the reasons set forth.

The Board desire to observe that the Act of Parliament itself here referred to, and not the Poor-Law Board, has imposed the duties rendered obligatory upon the Medical Officers under that Act.

All that this Board are able to do in the matter is, to point out to the Guardians of Poor-Law Unions the provision contained in the General Consolidated Order of the Poor-Law Commissioners, which enables them to give gratuities for extraordinary services rendered by their officers. Also, the provisions of the Statute rendering it competent to the Guardians to appoint persons in aid of their officers, where the duties they are required to perform under it would press too much upon the time of those officers. This course the Board has followed in very many instances, since the directions of the General Board of Health have been issued.

I am, Sir,

Your obedient servant,

W. G. LUMLEY, Assistant Sec.

To C. F. J. Lord, Esq., Honorary Secretary,

Committee of Poor-Law Medical Officers,
4, Hanover Square.

The General Board of Health,

Gwydyr House, Whitehall,

16th December, 1848.

Gentlemen,—I am directed by the General Board of Health, to acknowledge the receipt of your Memorial dated the 12th instant, calling the attention of the Board to certain provisions of the Nuisances Removal and Diseases Prevention Act, whereby they are empowered to require and enforce the performance of various duties in reference to Sanitary Regulations by the Medical Officers of Unions, and pressing upon the attention of the Board the injustice of enforcing the performance of such duties without awarding just and suitable recompense; and praying that the Board will deem it expedient to issue such instructions as shall give the Union Surgeons performing the duties of a Medical Officer of Health, a legal claim to remuneration.

I have to inform you in reply, that in the object of your Memorial,—namely, that the Union Surgeons should receive fair and adequate remuneration for the extra services which are required of them under the Nuisances Removal and Diseases Prevention Act, the General Board of Health entirely concur; but they have to call your attention to the fact, that the power of requiring the performance of those duties by the Union Surgeons, and the payment of all expenses which may be incurred therein, are left entirely with the Boards of Guardians, by the 12th and 14th Sections of the Act itself, and are not determined by the regulations of this Board, as you would appear to apprehend. The Board, therefore, are not in a position to enter upon questions of right, upon which they are not authorised to adjudicate, but that you may be made acquainted with the feeling of the Board upon the subject of remuneration for these extra services, I am to transmit to you, herewith, a copy of the 2nd Notification issued by the Board on the 31st October last, and to direct your attention to the following paragraph therein marked in the margin, which would appear to have escaped your notice:—

“It appears to the General Board of Health to be absolutely necessary, in the present emergency, to concentrate responsibility on the Medical Officers, and to

entrust them with discretionary powers, because the rapidity of the course of cholera will not allow them to wait for direction from the Guardians at their weekly meetings; and seeing the many arduous duties that devolve upon the Medical Officers, the General Board of Health cannot but express a hope that the remuneration of these officers will be more proportionate to the value of the services required of them, than it was upon the former occasion.”

I am, Gentlemen,

Your most obedient servant,

HENRY AUSTIN, Secretary.

To Thomas Hodgkin, Esq., M.D., Chairman, and Charles F. J. Lord, Esq., Honorary Secretary of the Committee of Medical Officers of Unions in England and Wales.

General Retrospect.

PATHOLOGY AND PRACTICAL MEDICINE.

NEW DIAGNOSTIC SIGN OF INTERMITTENT FEVER.

This sign, pointed out by M. R. Vanoya, consists in a peculiar condition of the mucous lining of the lower eye-lid. In a healthy subject this surface presents a more or less vivid red colour; but when intermittent fever has lasted some time in any subject, another appearance is observed, constituted by a pale crescentic line, the extremities of which correspond to the canthi of the eye, and its concave edge embracing the sclerotica: it is visible on lowering the lid and directing the subject to look upwards. This appearance is dispelled by the internal administration of febrifuge medicines, and persists so long as the patient is exposed to a relapse.

—*Medical Times.*

CYNANCHE PHARYNGEA FROM DISEASE OF THE MUCOUS FOLLICLES.

This disease, of which Chomel has observed twenty-two cases, although it is by no means of rare occurrence, has hitherto been overlooked. It consists of hypertrophy of the mucous follicles of the pharynx, soft palate, and uvula. It has been seen much more frequently in males than in females, chiefly at the age of from five to seventeen years. It often occurs along with a peculiar form of the upper jaw, in which the palatine arch is elevated, the cavity of the nose rendered smaller than natural, and nasal respiration to a great extent prevented. The upper lip in such persons is short, and the mouth is habitually kept open. Hence they are peculiarly liable to this disease from the perpetual tendency to dryness of the pharynx. Certain professions, as that of public singers, act as occasional causes of this disease. The first symptom complained of is a sense of uneasiness in the back part of the throat, with constant effort to get rid of the mucus which collects in that quarter. The patient has also a constant craving for water, which produces temporary relief. There is guttural cough and expectoration of small pellets of tough mucus, sometimes streaked with black. The voice of singers is contracted in range and impaired in quality, and patients in general have great difficulty in speaking aloud for any length

of time. These circumstances are apt to induce a suspicion of phthisis. On examination of the throat, the arch of the palate is seen to be covered by small red points, which are more thickly disseminated on and near the uvula. These become more numerous and larger as the disease advances, till at length they run into each other, forming ridges and raised patches, between which only a small part of the mucous membrane retains its natural appearance. The affection is essentially chronic in its progress; it does not endanger life, and sometimes disappears without treatment. It should be observed, that hypertrophy of the mucous membrane and follicles often exists in public speakers and singers, quite independently of disease, which produces no symptoms and demands no treatment. Gargles with borax or alum are generally sufficient to cure this malady in the earlier stages; should these fail, or should the morbid changes be considerable before treatment is commenced, cautious cauterization by the solution of nitrate of silver, or of nitrate of mercury, or by nitric acid diluted with three parts of water, and applied by means of a small piece of sponge, must be had recourse to. Baths, the douche, and the use of mineral waters containing sulphur, are also useful. Loud or continued speaking or singing must be avoided. The food must be well masticated, and must consist of articles perfectly free from acridity or acidity.—*Gazette des Hôpitaux*, June 1, 1848, and *Monthly Journal*, July.

SPIGELIA MARYLANDICA IN PRURITUS ANI DEPENDING UPON ASCARIDES.

Dr. Koreff gives two cases of rebellious itching of the anus, which yielded to this treatment after the fruitless employment of the usual remedies. The root is the only part of the plant which possesses the required virtue, the leaves being perfectly inert. The formula employed was as follows:—

Radici Spigeliæ dr. iss.
Mannæ oz. j.

To be infused in a pint of boiling water. Dose a cupful three times a-day, for three days. A concentrated decoction of the root may at the same time be used as an enema.—*Revue Médico-Chirurgicale*, Sept., 1848.

OVARIAN DROPSY.

Dr. Tilt closes an interesting series of papers on ovarian dropsy with the following practical deductions:—

1. That small and moderate-sized tumours may be cured by preparations of iodine given in large doses internally, as well as externally, the contents of the cysts being re-absorbed by the walls of the cyst, as in the cases seen by Dr. Rayer and Madame Boivin, or else voided per rectum, or per vaginam, as in many recorded cases.

2. That tapping the abdomen, if employed as a palliative, and without any view towards the radical cure of the patient, should be deferred as long as possible, modern statistics having confirmed Morgagni's opinion of the danger of this operation.

3. That when the cyst is voluminous, and felt bulging

in the vagina, there is a sufficient number of successful cases to countenance the puncture of the cyst per vaginam, an India-rubber sound being left in the cavity of the cyst, and moderate pressure being made to the abdomen.

4. That the rupture of the monolocular ovarian cysts, with the effusion of their contents into the peritoneal cavity, instead of being attended (as is even now generally supposed,) by the most alarming symptoms of peritonitis, is, generally speaking, unaccompanied by any alarming symptom whatever, thus warranting the subcutaneous incision of the cyst—an operation which has been successfully performed.

5. That the ulcerative opening of the cyst, after adhesion of its walls to the abdominal parietes, (the new plan of treatment I propose in certain cases of ovarian dropsy,) is supported alike by the complete success by which it has been followed, in the case I have recorded, and by the success attending a somewhat similar plan of treatment in hydatid cysts of the liver.

6. That ovariectomy should be reserved for cases of *multilocular ovarian cysts*, and those *monolocular cysts* where there is a considerable amount of solid deposit, unless from their diminutive size, or the absence of symptoms, they do not menace the patient's life by their rapid increase.—*Lancet*, Nov. 11, 1848.

LOCAL APPLICATION OF CHLOROFORM IN LUMBAGO.

Three cases of this disease are detailed by M. Moreau, in which immediate and permanent relief was obtained by the application to the loins of a piece of lint on which some chloroform had been poured. Oil silk ought to be laid above the lint, to prevent the evaporation of the chloroform. In a few minutes the patient complains of a burning heat in the part, which becomes red, and occasionally vesicles are formed; at the same time the rheumatic pain disappears. The author thinks that the cure cannot be attributed solely to the counter-irritation, as in one of the cases recorded sinapisms had been previously employed, without success. He supposes the chloroform to reach by imbibition the cutaneous and superficial muscular nerves, on which it exerts its anæsthetic power.—*L'Union Méd.*, Oct. 21, 1848.

In a case of pelvic tumour, where the patient suffered from severe pains of the inferior extremities, probably in consequence of the nerves being compressed in traversing the pelvis, the usual means of affording relief having failed of success, M. Legroux determined to try the local application of chloroform. A sponge containing chloroform was placed in the foot of a large boot of wax-cloth, constructed for the purpose, so that the vapour only came into contact with the skin. A feeling of warmth, prickling, and numbness, was soon experienced. The application was continued for several hours, when complete anæsthesia was established, and the neuralgic pains had entirely ceased. The absence of pain continued several days, and the same treatment was equally successful on its return.—*Ibid.*, Oct. 31, 1848, and *Monthly Journal*.

SURGERY.

WARTS OF THE VULVA.

It sometimes happens that the vulva is covered with a luxuriant growth of warts. "They are, in certain cases, so abundant as to dispart the labia, filling up the entire sulcus, and rising as a great convex mass of pale cauliflower-looking tumour, quite convex above the general level. Upon further separating the labia, so as to open the sinus pudoris, they are perceived to be small warty excrescences from the mucous body of the mucous membrane, and differ not from the warts on children's fingers except by their greater softness, which depends on their being always bathed with the sort of milky humour of the labial membrane. They often bleed when touched; and, when pinched off with the finger-nails, the broken surface trickles with blood, which soon ceases to flow. I have found that, when the entire labium, right and left, has been quite incrustated with warts as above, I could with the probe separate them anywhere; for they are distinct from, though in lateral contact with, one another. You will readily include a great number of them in a ligature, which, being tightly tied, they drop off after some hours. The readiest way to remove them is to snip them off, several at a time, with scissors curved on the flat. This being done, and the surface being lightly touched with the nitrate of silver pencil, or with a solution of sulphate of copper, the mucous tissue is not very likely to reproduce them".—*Females and their Diseases*. By Professor Meigs. Philadelphia, 1848.

CONCLUSIONS RESPECTING GUN-SHOT WOUNDS.

The facts established by the recent events in Paris are as follows:—

1. The appearance of gun-shot wounds depends on the time of the occurrence of such accidents; at an early period the wound of entry is larger than that of exit. Suppuration being once established, there is a difficulty in distinguishing the two; further on in the process the characters become again well marked.

2. In civil hospitals, contra-distinguished from those attached to a moving army, more may be done to save limbs than is commonly thought.

3. With respect to the removal of foreign bodies, the mass of evidence is in favour of such a proceeding. Exceptional cases may occur.

4. In primary hæmorrhage we must act as in the case of other wounds, tie the artery as near the wound as possible. In consecutive hæmorrhage, on the contrary, we must put the ligature on the main trunk.

5. Secondary amputation should never be thought of as a thing to fall back upon; amputation should be primary, or not at all.

6. *Débridemens* should be strictly confined to freeing aponeurotic structures in a state of constriction.

7. In matters of treatment, our old English system seems best,—cold water dressings instead of ice; when the skin is broken, the latter is inadmissible.

8. As a general rule, the part should be disturbed as little as possible, the pulse and tongue being sufficient indices of the state of the health of the patient.

9. Operations should never be performed in a state of collapse.

10. Age and mental conditions seem to have much to do with the mortality. According to M. Baudens, officers are cured with more difficulty than common soldiers; generals generally died.

11. Anæsthetic agents have in most cases proved safe and beneficial.—*Medical Times*, Nov. 4, 1848.

EMPLOYMENT OF COLLODION IN FISTULOUS OPENINGS.

Dr. Yvonneau, of Blois, relates the following case:—A little girl, five years old, was brought to me, whose right cheek was totally perforated very near the commissure of the lips, in consequence of an abscess which had burst externally, and which had, very neglectfully, not been opened early within the mouth. Both the upper and lower jaw were attacked by caries, and the cheek had formed adhesions with the gums. The part had the shape of a funnel, the apex formed by a fistulous opening, about half an inch in diameter, through which the saliva and the liquid taken into the mouth were dribbling. The continual loss of saliva gave the child an inordinate appetite, in spite of which it was wasting very much. The breath was also extremely fetid. I operated on the 11th of October, in the following manner:—After having rendered the child insensible by chloroform, freed the adhesions, and removed a portion of the lower jaw which was detached, I then included the fistulous opening in two semicircular incisions, and brought the lips of the wound together. These were kept in contact by a twisted suture upon four needles and strips of adhesive plaster, and a roller around the chin finally contributed in keeping the parts steady. The whole of the dressings were, however, very soon so much soaked with saliva that they would have had to be changed every two or three hours to give a chance of keeping them clean. The third day after the operation I perceived that portions of the liquid which the child drank found their way through the fistula as previously; the parts had ulcerated upon the needle and the fistulous opening was larger than before. Puzzled and annoyed at this failure, I bethought myself of using collodion, which I had employed before with benefit in the place of dextrine for applying bandages to fractures. I obtained perfect stillness in the child by chloroform, and the margin of the wound being exactly brought together by an assistant, I placed strips of very good adhesive plaster across it in an imbricated manner, which included the chin, the cheek, and the ala nasi, and by means of a camel-hair pencil I covered the whole with a layer of collodion. I expected thereby to render the plaster not only thoroughly adherent, but impermeable to the saliva. Three days afterwards I was obliged to remove the dressings, as the child had amused herself by pulling off a strip, and in doing so I was very agreeably surprised to find the wound covered with granulations, and the fistulous opening reduced to a line or two in diameter. Full of expectation, I re-applied the dressings in the same manner as above. I did not interfere with it for the five following days,

when I cut away the apparatus, and found, instead of the ugly foramen, a clean linear cicatrix, which will be almost effaced by time. The colloidion has evidently been of very great service here, for not only did it prevent the imbibition of the dressings from capillary attraction externally, but also effectually prevented the saliva from coming in contact with the external part of the wound, and thereby favoured the formation of granulations in the latter. Is it not probable that strips of adhesive plaster thus applied will very conveniently replace the needles in the operation for hare-lip?—*Union Médicale* and *Lancet*, Dec. 23, 1848.

OBSTETRIC MEDICINE.

QUININE A PROPHYLACTIC OF PUERPERAL FEVER.

During an epidemic of puerperal fever, which occurred in the hospital of Rouen in 1843, the thought occurred to Dr. Leudet of ascertaining by experiment whether quinine possessed the power of enabling the economy to resist the contagion of this disease. From the 21st September 1843 to the 8th January 1844, 83 women were delivered in the Hôtel Dieu of Rouen; in nine of these women to whom quinine was given, not one case of puerperal fever occurred, while of the remaining 74, who received no special treatment, 21 suffered from the disease. In two later epidemics, its utility was subjected to a more extensive trial. From the 8th of July to the 9th of August 1845, of 26 cases of delivery, 15 were treated with quinine; one only of these was attacked, while of the remaining 11, eight had puerperal fever. Lastly, during an epidemic which prevailed in Rouen, from the 19th of March to the 21st of April 1846, there were 36 deliveries. Quinine was prescribed to 17 women, only one of whom had fever, while of the 19 who were submitted to no special treatment, 11 were attacked with the disease.

Dr. Leudet begins the prophylactic treatment about four hours after delivery, by the administration of five grains of quinine, which dose is repeated twice during the same day, at intervals of five hours. On the second day the same doses are given; but on the third day they are diminished to three grains thrice daily, and are so continued for four days more.

This method is adapted for the more common form of epidemic, where the fever does not present itself for three or four days after delivery. When it appears during parturition, or immediately after it, Dr. Leudet advises that the use of quinine should begin with the first symptoms of labour.—*Thèses de Paris*, 1847, from *Monthly Journal*.

CONTUSION OF THE SCROTUM IN BREECH-PRESENTATION.

Van Hoeslorbeck calls attention to contusion and consequent gangrene of the scrotum as a not unfrequent event in breech-presentations. Having met with three cases in which the child died from sloughing of the parts, he has since always adopted the precaution of pushing the scrotum up above the union of the thighs, and preventing its descent by mechanical means.—*Revue Médico-Chirurgicale*, Sept., 1848.

RETROVERSION OF THE UTERUS DURING PREGNANCY.

M. Van Heugel relates a case in which spontaneous reposition of the uterus took place after emptying the rectum and colon of an immense quantity of impacted fæces.

A young woman, three months advanced in pregnancy, experienced great difficulty in making water, with pain in the abdomen. On examination the os uteri was found under the pubes, and the fundus projected upon the sacrum, and depressed into its hollow. The urine was drawn off, and a large enema was exhibited by means of a tube, which was passed up to the sigmoid flexure; an enormous quantity of scybala were thus removed, and upon a subsequent examination it was found that the fundus had resumed its natural situation.—*Revue Médico-Chirurgicale*, Sept., 1848.

LITERATURE OF THE NINETEENTH CENTURY.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

A friend, desirous of placing a son with a medical man, inserted in one of the London papers an advertisement to that effect. Amongst numerous answers, he received one, of which I enclose you a *correct* copy. Its singularity will, I am sure, amuse you; and possibly you may deem it worthy of a corner of your Journal for the amusement of your numerous readers.

I am, Sir,

Yours faithfully.

T.P.F.

Kimbolton, Oct. 16, 1848.

(Copy.)

There will be a vacancy at ——— when your Son may have ample time to prosecute with vigour his studies, In the Branches of Clinical practice, the science of Pharmacy, Materia Medica in the Intimate or Ultimate principles of Research. The Physical operational intuitive elements during the varied precession of the Analytical and Synthetical Systematology of Chemistry as applied to the spheres of The Physician whilst he shall have the advantage of my experience in artial Chemistry and Practice, blent with the elements of the Psychologician should you place him under my roof. There I will gurantee him ample leisure with the privilege of attending my vindications of each immediate referential influence and the developable action of such on or over the Physical structure in the Laboratory, whilst he may prosecute the higher branches of Anatomy and the general Classifications of the Pharmacopœia either in this city or with me at the Scene of General duties. The spot is famed for its magnificent clime, in point of Salubrity, the grandeur of its scenery, the ample means, easy and moderate of access, whose adjacent Islands, Lochsides, and teeming vales abound with the most sublime elements of natural and physical beauty and fertility for the opening mind of the young student. There the Occuminal features of the Physical scholar's health and the wealth of his mental forces will be at liberty to expand and be fertilized, whilst the harmonious laws that regulate the march of the Savant, during the hourly

revolutions of his onward investigations, will be patiently submitted to the studential inquirer. His mind will not be fettered by rigid dogmatisms nor injured by a too late system of Characedic experimentalization. He may have private apartments attached or apart from the sphere of action, as shall be thought best.

I have the honour, &c.

FALKNER'S LIQUOR OPII SEDATIVUS.

The testimonials in favour of this lately-introduced preparation are so decisive and unquestionable, that we feel it our duty to recommend it to notice. Like Mr. Battley's solution, its exact composition has not been made known, but we have no hesitation in stating that it is possessed of many advantages as a sedative, and is especially capable of being employed with relief in cases where other opiates cannot be borne. Mr. Cole, the House-Surgeon of the Worcester Infirmary, states that it has been for some time used almost exclusively in that Institution, and is much approved of by the medical officers. We have also seen it highly spoken of by Mr. John Pemberton, House-Surgeon to the Droitwich Lunatic Asylum; by Dr. Rootes, of Ross; Messrs. Walsh, of Worcester; Broughton, of Ruyton; Potheary, of Munslow; Cooke, of Newent; Williams, of Talgarth; Wilding, of Church Stretton; and others who have made trial of it.

It was intended by Dr. Hastings, who is well acquainted with its merits, to draw attention to this preparation at the Anniversary Meeting of the Provincial Medical and Surgical Association, at Bath, held in August last, from which, however, he was prevented by the pressure of other matters of importance.

Medical Intelligence.

APPOINTMENTS.

John Topham, M.D., has been elected Physician, and E. F. Dehane, G. Edwards, and J. T. Cartwright, Esqrs., Surgeons, to the South Staffordshire General Hospital, Wolverhampton.

George S. Jenks, M.D., Fellow of the Royal College of Physicians, has been elected Physician to the Sussex County Hospital, Brighton, in the room of Dr. Blair, resigned.

M. Berard, Professor of Physiology at the Faculty of Medicine, Paris, has been appointed Dean of the Faculty, in the room of M. Bouillaud, superseded.

M. Velpeau has been elected President, M. Bricheteau Vice-President, and M. Gibert, Secretary, of the Academie de Médecine, Paris, for the year 1849.

Matthew Talbot Baines, Esq., has been appointed Poor-Law Commissioner for England, in the room of Mr. Buller, deceased.

SOCIETY OF APOTHECARIES.

Gentlemen admitted Licentiates Thursday, December 21st, 1848:—Robert Ingram Stevens, London; James Bernard Rack, Prestbury, near Cheltenham; William Henry Slade, Frome; John Marsh, Mansfield; Robert Savignac Stedman, Great Bookham, Surrey; Thos. Coutts Morison; George Harpley Beck, Norfolk;

Pryce Jones, Helmston, Hants; Nicholas Marsh, Liverpool; George Carfrae Hope, London; Frederick John Earle, Winchester; Thomas Selby Blanshard; Philip James Elborough; Samuel Weston, Devenish; Banfield Teague Vivian, Corwan, Cornwall; Frederick William Armstrong Rawlins, Congleton.

Thursday, December 28th:—John William Leacroft, Derby; David Hope, Deptford Bridge.

OBITUARY.

Died, December 19th, aged 77, at Cheltenham, William Greaves, M.D., late of Mayfield Hall, in the county of Stafford, a Magistrate for the counties of Stafford, Derby, and Gloucester.

December 20th, at Brighton, aged 66, George Drysdale, M.D., R.N.

December 20th, aged 49, Thomas South, Esq., Surgeon, of Judd Street, Brunswick Square.

December 22nd, in Russell Square, aged 62, James Cowles Prichard, M.D., one of the Commissioners of Lunacy. Dr. Prichard was formerly in practice in Bristol, and well known as the author of several excellent works, in particular by his researches on the "Physical History of Man." On the occasion of the meeting of the Provincial Medical and Surgical Association at Oxford, in the year 1835, Dr. Prichard read the Address in Medicine, on which occasion the Degree of Doctor of Medicine in that University was conferred upon him.

December 26th, at Oxford, Charles Lewes Parker, M.A., Surgeon to the Radcliffe Infirmary, Oxford.

December 29th, in Finsbury Square, aged 68, William Martin, Esq., Surgeon, R.N.

BOOKS RECEIVED.

The Cholera at Malta in 1837. From the Italian of Giuseppe Stilon, M.D., &c., &c., Physician to the Cholera Hospital in Valetta. By Seth B. Watson, M.D., &c. London: Churchill. 1848. pp. 178.

PROVINCIAL MEDICAL & SURGICAL JOURNAL.

A COURSE OF LECTURES ON SURGERY,
DELIVERED IN THE
MEDICAL SCHOOL OF CAMBRIDGE.

By GEORGE MURRAY HUMPHRY, Esq., Downing
College, Surgeon to Addenbrooke's Hospital.

LECTURE I.

Relation of Local Disease to the Constitution; Good Constitution; Constitution enfeebled by Defect or Want of Harmony of great Organs, by impaired or naturally weak State of Assimilative Functions; Varieties of Characters of Disease with Age; Constitution may be benefitted by, or habituated to, Local Disease; Disease, a modification of Nutrition.—Inflammation, reparative and destructive; Changes observed in the former consist in an Exaltation of Natural Forces—may be Healthy or Morbid: Effects of Inflammation vary according as Decay or Reproduction are most accelerated by it.

The state of the patient's constitution, and its relation to the local disease under which he suffers, is so important an object of attention in the study and practice of surgery, that I will commence by a few remarks upon this subject.

That person is said to enjoy a good constitution, in whom each of the great organs of the body does its duty well, and in whom they are all well balanced, and in harmony with each other, the nutritive and assimilative processes throughout the system being conducted vigorously and efficiently, so that repair is equal, or nearly equal, to decay. The man thus happily constituted is able to resist many of the exciting causes of disease, to which others of weaker frame fall victims. His accidental maladies are chiefly of an inflammatory nature. The morbid process, partaking of the active character of his healthy functions, advances rapidly, and is attended with well-marked inflammatory fever, in which all the great organs of the body sympathise equally, and in due proportion to the severity of the local affection. The disease demands, and the patient will bear, active treatment, and the case proceeds quickly to a favourable or fatal termination. The gradual decay of age takes place in its appointed time and manner, obedient to laws originally impressed upon the body, is shared by all the organs alike, and is as natural as their development and advance to maturity.

Such perfection of physical formation is, however,

comparatively rare; very frequently the constitution is weakened by a defect in one or other of the great organs, which may be the result of original imperfection, of too early decay, or it may be the effect of disease. The whole body is, by this fault in one of its parts, rendered more amenable to the influence of disturbing causes, and the impression produced upon the system by a local affection is often, under these circumstances, greatly disproportionate to its severity. We are startled at the rapidly fatal effects of an attack of diarrhoea, or an inflammation of the leg, such as we are accustomed to treat with the assurance of success, but the *post-mortem* examination explains the mystery, by revealing an unsound condition of the heart, an imperfection in its valves, or degeneration of its muscular fibres. In one man, a broken leg is followed by an attack of gout; in another, by jaundice; in a third, by delirium; and in a fourth, by palpitation of the heart, with an intermitting pulse, the effects of the shock calling forth the constitutional predisposition, and telling most upon the weakest organ.

Another cause of constitutional weakness consists not so much in unsoundness of any of the great organs in particular, as in a want of due proportion or harmony between them; one or more preponderating over the others, wearing them out, and giving a peculiar character to the diseases which occur. In the plethoric habit, the circulatory system prevails, and disease is chiefly of an inflammatory nature. A small spark is sufficient to light up the flame, but the accompanying fever is not generally so well marked, of so sthenic a character, nor is depletion so well borne as in the more healthy person.

The predominance of the nervous system is especially shown in the affections occurring in sensitive and hysterical persons. The symptoms are essentially of a nervous character, and the system responds so violently to a slight impression, that a severe fit, with complete insensibility and convulsions, may follow a sudden fright, a slight injury, or an attack of indigestion. The pain attendant on a local inflammatory attack is also more or less disproportionate to the other symptoms, or, perhaps, it lingers on after they have subsided, so as to constitute the entire disease; and a very troublesome disease it often proves, resisting all the ordinary means the surgeon can devise, and yielding, perhaps, at last, to some accident, a blow, or strong mental impression.

The hysterical affections of joints are good examples of this class of complaints. A young woman suffered under acute pain, and exquisite tenderness of the ankle-joint, which had continued for months, rather aggravated by the leeches, blisters, and other means employed for her relief. Her health was not much impaired, and there were no appreciable signs of disease in the joint, no swelling, heat, nor crepitation. I spoke to her in a very decided manner, desiring her to leave her bed, and move about the ward. In two days she was walking about, and soon after was discharged from the Hospital. She walked a little lame for a long time, and now (more than two years since she left the Hospital,) she feels weakness, and some uneasiness in the joint, when the weather changes. I do not wish to persuade you that there is actually no disease in cases of this kind, for I believe that there generally is some slight inflammatory condition of the joint or limb, though it is by no means proportionate to the pain and tenderness complained of. It is no very easy matter to assign a true value to the symptoms which are conveyed to us by the expressions of the patient; and as, on the one hand, undue importance is often attached to the local affection of a sensitive patient, so, on the other, I have frequently known the existence of real disease to pass unnoticed, or to be discredited, because the pain and accompanying nervous symptoms were extreme, or of an hysterical character.

The sense of pain often becomes more acute, and the ability to control the emotions less strong, when the system has been weakened by protracted illness and much suffering. Under these circumstances we sometimes witness strange nervous symptoms and hysterical attacks, in persons who had not previously shown any disposition of the kind.

In like manner the pain experienced during an operation, and the effects of the shock upon the system, vary greatly with the nervous susceptibility of the patient; and it is one of the great advantages of anæsthetic agents, that their influence is most easily and certainly induced in delicate and sensitive persons, or in patients who have been weakened by long protracted disease, those very cases in which the pain and shock of an operation are most to be dreaded.

An impaired condition of the assimilative functions, primary or secondary, or both, is also one of the most common causes of constitutional debility, and is a very fertile source of local disease. To instance one class of cases of this kind:—There are many persons who are unconscious of any particular ailment, perhaps are not aware that they suffer from indigestion, have good appetite, and are capable of exertion; but their complexion is not clear, the tongue is habitually white, and the urine high coloured and thick; they perspire easily, or suffer under frequent attacks of diarrhoea. The disorder is not necessarily confined to the stomach and chylipoietic system in particular, but may be diffused over the whole process of digestion, from its commencement in the mouth to its completion in the blood, so that crude or imperfectly-assimilated materials find their way into the circulation, and pass off by the skin, the kidneys, or the bowels, or give rise to a disordered

state of the nutritive processes generally. Such a condition is likely to be induced by long-continued intemperance in eating or drinking, by sedentary occupations, by over anxiety, late hours, &c. You will find that a large proportion of gouty affections, sore legs, boils, diseases of the cellular tissue, and a variety of local ailments, are associated with some such disorder of the alimentary system. Hence the paramount importance of general therapeutical treatment in cases of this kind, particularly attention to diet, which is the more necessary to enforce, because the patients do not always suffer the direct symptoms of indigestion referable to the stomach.

Here I would, in passing, just warn you against running into the extreme of attaching too much importance to the stomach and digestive system, to the entire neglect of the local disease. A person suffers the symptoms of slight inflammation of the bladder, which is observed to vary with the state of the stomach, and to be so constantly aggravated by indiscretion in diet, that the friends encourage the idea of the affection being "all stomach;" and the surgeon is induced to express the same opinion, which he regrets having done when the local disease, assuming more importance, is less influenced by accidental causes. A more careful consideration of the case would have informed him that, though the symptoms referable to the bladder were greatly influenced by the state of the digestive system, their existence under any circumstances was an evidence of disease, or disposition to disease, in the organ itself.

When the assimilative processes throughout the system are habitually conducted in a feeble, rather than a disordered manner, slight inflammatory affections are of frequent occurrence, which are languid in their progress, and difficult to cure. Of this state of constitution, and the character of the diseases to which it is liable, I shall speak more at length when describing the pathology of scrofula.

I must not omit to mention a few of the peculiarities of disease dependent on the time of life at which it occurs. The thread of life, strongest in the middle, tapers at either end; and in the infant and old man a very little will suffice to snap it. In the adult the vital powers are greatest, and the characteristics of the morbid processes most fully developed; the descriptions of pathology and rules of treatment are, therefore, usually to be understood to relate to that period of life, unless it be otherwise expressed.

The fine soft delicate frame of the child is peculiarly susceptible of disease, which may be easily communicated to it by contagion or atmospheric influence. The nervous system, in advance of the rest of the body in regard to its development, is highly sensitive; and a slight amount of local irritation, or the commencing stage of inflammation, is attended with great constitutional excitement, so that, judging from the high fever, the quick pulse, hot skin, and furred tongue, we may easily fall into the error of over-estimating the severity of the local affection, and of being over-active in its treatment. The rapidity and violence with which the nervous system sympathises with a local disorder, render slight complaints, such as teething, of serious

importance. Indeed, children often die of the constitutional disturbance, before the local disease has sufficiently advanced to leave any traces discoverable on a *post-mortem* examination. Hence it is, that in a very considerable proportion of the autopsies of infants all the organs appear to be perfectly sound, and we are at a loss to assign the cause of death, if we have not been acquainted with the symptoms that existed during life. Hence it is, too, that children often recover, and recover rapidly, from the most alarming attacks, when the slight cause which occasioned them has passed away. This high nervous sensibility, and disposition to acute sympathetic disturbance, furnishes an important indication of treatment in the diseases of children,—viz., that remedies should be directed to meet the tendency to excitement at the same time that measures are taken to remove the exciting cause. The necessity of adopting this plan more largely, of resorting to the cautious employment of sedatives, and of depleting less actively, is daily becoming more felt.

It should be remembered, too, that children are easily depressed as well as excited;—that they bear depletion ill, and recover slowly from its effects;—the amount of fibrine contained in their blood is comparatively small;—their textures are delicate, and yield quickly to the destructive effects of disease.

Nevertheless, it is to be remarked, that their reparative powers after injuries are great, provided they rally from the effects of the shock, and provided there has not been much loss of blood. The inflammation which follows has a disposition to stop short in the reparative stage, and does not so commonly run on to the destructive stages as in the later periods of life. It may strike you that burns form an exception to this statement; but the fatal result which so commonly follows in these cases is, for the most part, due to the continued depressing influence of an extensive injury of the skin. The children either die of the direct shock, or rally but imperfectly, linger in an enfeebled state, so that they are easily influenced by the exciting causes of disease, and a slight attack carries them off.

The peculiar features of the diseases of old age are, in great measure, owing to the failing vital powers of the whole system, and of those organs more particularly which happen to have been gifted with less endurance than the rest. There is not much scope for treatment, and the old man often shews an instinctive aversion to medicine. The inflammatory affections of this second childhood may, in many respects, be contrasted with those of infancy. The dry harsh frame of the old man is much less susceptible of atmospheric influences and contagion than the delicate system of the child; but it suffers more severely from injuries, for the reparative powers are feeble, and the inflammation induced in this or other ways soon passes on to the destructive stages of ulceration or mortification. The constitutional symptoms of inflammation are rather those of depression and exhaustion than of excitement; the fever is of low type, attended with dry brown tongue, quick soft intermitting pulse, muttering delirium, and so on. Depletion is ill borne: soothing and supporting measures are required. The old man, like the child, is easily prostrated by the onset of disease, and

often dies in the very first stage of an attack. Perhaps he is found dead in his bed, having yielded without struggle enough either to have furnished any premonitory symptoms of immediate dissolution, or to have enabled the disease to affix discoverable marks of its existence to any particular organ.

As a general rule it may be assumed, that the existence of local disease is prejudicial to the general health of the patient. But even this statement admits of some exceptions. For instance, a person who has been suffering general indisposition for some months, is greatly relieved by the appearance of a cutaneous eruption or a sore leg; and the sudden suppression of the external malady would in all probability be followed by the occurrence of some more dangerous internal disease. Again, a healthy man becomes the subject of an ulcerated leg in consequence of a blow, a compound fracture, or other accidental cause. In course of time the system becomes so habituated to the disease, that its removal is followed by sinking at the epigastrium, sense of fulness of the head, or even apoplexy. Remarkable examples of this kind are related in the case of persons who had so long suffered from the stimulus of pain caused by stone in the bladder, that the loss of the stone, like that of an habitual dram, was followed by prostration of strength, and some other stimulus was required to supply its place. It is an humbling reflection that we cannot always boast even of our cures; and unless we are in the habit of attending closely to the relation which local diseases bear to the constitution, our patients will often have reason to regret the application of our successful but ill-timed measures.

I would advise you, before commencing the study of pathology, to make yourselves well acquainted with the information on the subject of nutrition contained in modern works on physiology. For you must know that disease is but a modification of the ordinary or natural processes of nutrition; and the extension of disease from one part of the body to another is, probably, no more than a result of assimilative operations, similar to those by which the textures grow and are repaired. In the simple diseases, such as inflammation, the morbid process seems to assimilate to itself, or alter, the healthy nutritive forces of adjacent parts, impresses its peculiar character upon them, and so spreads by radiation from a single point, till the whole system is involved in it. In the specific diseases the same influence is still more remarkable. A cancerous tubercle spreads by the assimilation to itself of the neighbouring structures, which it effects so completely that the natural texture of the part is lost, and the new formation occupies its place. There is, as it were an incessant conflict between the assimilative influence of the disease and the natural forces of nutrition; and the former spreads in proportion as its own energy is great, or the resistance of the tissues to its progress is feeble. Thus cancerous tumours are often first observed when the patient's strength has been lowered by illness, anxiety, or other cause; they grow with increasing rapidity as the powers of the system give way, and in the latter periods of the illness they are propagated to distant parts, which had hitherto

held out against them. In the tertiary stages of syphilis, the increase of the malady and the strength of the patient are often found to alternate with one another, and when our specific remedies have lost their effect, we are content to endeavour, by improving the general health, to keep the disease in check.

Having made these few general remarks for the purpose of directing your attention to the important subjects referred to, I will at once proceed to consider the process of inflammation, which will occupy much of our time, because, in one or other of its stages, it is the source of a very large proportion of the diseases afflicting the body, besides being, at some time or other, more or less intimately associated with nearly all those morbid conditions which do not directly originate in it. It is also frequently much under the influence of treatment, preventive as well as curative; and it presents further claims to our favourable consideration, on account of its being one of the means by which solutions of continuity, occasioned by injury or disease, are repaired, and the integrity of the body preserved. We have, therefore, to consider the reparative no less than the destructive effects of inflammation. We may complain that by its severe attacks the textures are mutilated, and softening, ulceration and mortification engendered; but we must not forget that it carries the balm of healing with it, or that by its milder influences abscesses are opened, ulcers closed, and dead parts detached,—that wounds are healed and fractures united. I am aware that on this point—the threshold of surgical pathology, you will meet with much disputation. You will find one eminent writer upholding inflammation as the great safeguard against the injurious effects of wounds, and stating that without it the lancet prick in venesection would be fatal; while another takes quite an opposite view, sees only its destructive effects, and will admit it to have no share whatever in the salutary processes of reparation.

These contradictory statements are the expressions of opinions in reality less at variance than they appear to be, and result from the different limits assigned to inflammation by the respective authors, rather than from their views of the real nature of the process being so greatly opposed. They may, I think, be reconciled without compromising the opinions of either party, if we will only admit that there are, in inflammation, two chief stages, so dissimilar in their effects that they would scarcely seem to belong to the same process, yet so closely allied in their nature that it is difficult to point out the characteristic marks which distinguish them; and they pass into one another so frequently and insensibly, that the difference is clearly one of degree rather than of kind. These we will distinguish as the reparative and destructive stages of inflammation, and will proceed to the consideration of the former.

In the ordinary state of the circulation, the blood moves through the capillaries in a gentle equable stream, propelled by the force of the heart's action, which has been modified by the elastic influence of the large arteries, and is assisted by the contractile power of the smaller vessels. The red corpuscles float along

in the middle of the current, showing little disposition to adhere together, or to the walls of the vessels; whereas, the white corpuscles, which are of lighter specific gravity, occupy the exterior of the stream, travel less rapidly, and are often seen resting for a time against the sides of the tubes. The fluid elements of the blood soak through the walls of the vessels, permeate the surrounding tissues, and become subservient to their nutrition. The small vessels possess, besides, a certain distributive power over the blood, independent of the central organ, whereby they are able to regulate the local circulation in obedience to the necessities of the part; so that if any particular organ be used more than the others, its supply of blood may be increased without disturbing the general circulation. It is probable, too, that they exert some control over the quantity and quality of the liquor sanguinis which is filtered through their walls for the nourishment of the adjacent structures.

The simplest deviation from the ordinary condition of the circulation in a part, is that which is brought about to make amends for the extraordinary wear and tear consequent upon unusual activity of function, and consists in an increased action of the small vessels. "*Ubi stimulus ibi fluxus.*" The sense of fullness and heat of head after intense application, indicates that the vessels of the brain are busily employed in supplying the materials for active nutrition. They are dilated beyond their usual size, and the blood is passing more rapidly through them. The organ is in a state of active congestion. A similar change occurs in the neighbourhood of a healing wound or ulcer, in obedience to the extraordinary demand made upon the circulatory and nutritive powers, for the purpose of effecting the reparative processes; and the enlarged tortuous arteries of the pregnant uterus, are the result of the same condition long continued. This increase of energy and activity is not confined to the small vessels, it extends in like degree to the blood flowing through them. The several stages of cell-formation are completed more rapidly, the corpuscles are seen to accumulate in greater numbers, and their products, more particularly the fibrin, are proportionately increased and endued with higher powers of organization, so as to suffice not merely for the nutrition of wearing tissues, but also for the formation of new structures in the place of those which had been destroyed; or for the development and growth of a new being. In like manner these changes may be communicated from the part to the whole system, from the blood flowing through the excited capillaries to that circulating in other regions, and from the minute vessels to the heart. The state of the circulation and of the blood in the pregnant female, and the rapidity and force of the heart's action, together with the general heat of the body occasioned by unusual exertion, are familiar instances of this.

Such a condition, affecting a part or the whole system, we will call the first or reparative stage of inflammation, which is to be understood, therefore, as consisting simply in an exaltation of the ordinary forces of circulation and nutrition, occasioned by an unusual demand upon them, and taking place in

consequence of unusual exertion, or to effect some reparative process. It results from a natural stimulus, involves the several parts concerned in nutrition—the blood, the vessels, and the textures, in due proportionate degree, and is to be regarded as no other than a healthy and orderly action.

It may seem an inconsistency to apply a term usually expressive of disease to a process so salutary, and, indeed, essential to the preservation of the body, as I have described this to be; but I do so for the purpose of impressing upon you, at this the starting point of pathological investigation, that there are no broad lines of demarcation between healthy and morbid processes,—that they pass into one another by insensible gradations,—and that the same process may be healthy or morbid, according to the circumstances under which it occurs.

This reparative stage of inflammation borders very closely upon, and may even of itself constitute, disease. It does so when it exists without any definite end to be attained,—when there is no increased activity of function,—no wound or ulcer to be healed. Under such circumstances it is an injurious process, a morbid congestion, and may give rise to exuberant or unhealthy nutrition, to hypertrophies, warts, and such like structural alterations, to which effects we shall subsequently recur. Or, commencing in a natural manner, and for a desirable purpose, it may easily exceed its normal bounds as a reparative process, and pass on to that which I have called the second or destructive stages of inflammation.

The application of an extraneous stimulus or irritant is attended with precisely the same results as the natural stimulus of increased function; both occasion the same state of active congestion, the same excited condition of vessels, the same accumulation and rapid formation of globules; and the term which is applied to the altered condition in the one instance, should be retained in the other, though the circumstances under which they occur, and the ends accomplished by them, may differ.

This state of active congestion is readily produced, and may be seen by irritating the transparent membrane of a frog, or other animal, under the microscope. The orderly progress of the blood is seen to be disturbed, the corpuscles hurry about confusedly from point to point, the vessels become dilated, the blood continues to pass rapidly through them, and there is a considerable afflux of blood to the part. Blushing, and the red circle you have, doubtless, often observed round the place where you have been making a caustic issue, are instances of the same.

I must, however, tell you that some pathologists, arguing rather from probabilities than from the observation of facts, are strenuously opposed to a belief in the state of active congestion, such as I have described it to you. They regard the process of inflammation in all its stages, as consisting in a relaxed or paralysed condition of vessels, accompanied by a retardation of the current of blood in them. We may not, it is true, be able to explain, by physical laws, in what manner dilatation and accelerated circulation can be contemporaneously effected in the same vessels,

any more than we can understand how the minute vessels assist in the circulation at all; but the general appearance of the inflamed part, the bright red colour, the additional heat, the thumping arteries, and the turgid veins, are sufficient evidence that such is really the case, exclusive of the more direct proof furnished by microscopical observation. There is no difficulty in conceiving that such a condition results from an exaltation of that distributive power resident in the vessels of each particular part, which is generally allowed to exist; active congestion, in short, consists in nothing more than an increased energy of circulation, of the same kind as that which must be of continued occurrence in each organ to meet its varying function. I do not think the objectors to this view have ever given a satisfactory explanation of the turgid state of the veins of an inflamed limb, or of the fact that an increased quantity of blood passes through them, which has been shown by the experiment made by Mr. Lawrence, of opening corresponding veins in both arms in a case of inflammation of one hand, the flow of blood being in the fullest stream from the inflamed limb.

One of John Hunter's experiments illustrates this dilatation of the vessels. Having excited inflammation in one ear of a rabbit, and injected the head from the aorta, he found the arteries of the inflamed ear enlarged one-third beyond their natural size, and arteries were injected in it which had no visible counterpart in the other ear. The enlarged vessels admitting injection more freely, or a greater number of red corpuscles than usual, have led persons to think that new vessels are actually formed in a part during inflammation. This, however, appears very rarely to take place.

It seems probable that the analogy between active congestion, when existing as a disease, and that occurring as a natural phenomenon, in consequence of increased function, is not confined to the condition of the blood of the vessels, but that it may be extended also to the changes which take place in the tissues; for the delay and reproduction of particles appear to be accelerated under both circumstances, in the one as a cause, and in the other as a result, of the process. Parts not unfrequently become hypertrophied, as I have already mentioned, and the researches of Dr. Bence Jones show, that the excretion by the kidneys, of large quantities of phosphate of lime, is a frequent occurrence in the early stages of inflammation of the brain, the same salt being also in excess after great mental exertion.

As we proceed with the subject of inflammation, we shall find that its effects upon the tissues vary according to the proportion in which it influences the decay or the reproduction of their particles; and that its effects are on the whole most manifest on the structures whose transmutation of particles is most rapid. In the early or reparative stage, reproduction is in excess, giving rise to the healing of wounds, or the increase of hypertrophies. In the later stages the accelerated decay and dissolution of atoms is not counterbalanced by a corresponding rapidity of reproduction; on the contrary, nutritive processes both in the blood and in the tissues are alike impaired or disordered, and as

a consequence of these two effects,—increased decay and impaired nutrition, the various destructive results of inflammation, atrophy, softening, interstitial absorption, ulceration, and mortification, are engendered.

THE

CONTAGION OF ASIATIC CHOLERA.

By E. O. SPOONER, Esq., Blandford.

It is now more than three months since the pestilential cholera has been reported among us. Has it swept over the land as an atmospheric influenza? Has it followed any definite track of the wind, or any regular direction of the compass? Has it been attended with any new or unusual atmospheric phenomena? Has it followed any geological formation, or mineralogical peculiarities? From the tertiaries of the London bason, up to the granitic series of Edinburgh, it has appeared with strict impartiality. It lurked about in the fine weather of October, in the wet month of November, and at Christmas it was reported at Belfast, in Ireland, having taken ship from Glasgow. On board one of the emigrant ships from Bremen, it has crossed the Atlantic to New York. All the western ports of our island, however, and all the Channel harbours, have been free from invasion. *They have no extensive trade with Riga, Hamburg, or any of the northern pest ports.*

More than three months ago we were told on authority that it might at any time be expected to jump out of any uncleaned cesspool, or undrained ditch; all our villagers' pigs were forthwith ordered to be killed, for pigs and pigsties were voted "nuisances." Like the fabled "wandering Jew," this swarthy Asiatic was said to be out on his travels through the land, and that he took lodgings in these appropriate localities. Ditches and cesspools are quite as common at Liverpool as at Leith; quite as numerous at Bristol as at Hull; yet, neither Liverpool nor Bristol have yet reported any cases, notwithstanding the stringency with which reports are hunted after, and although three months have elapsed since Hull received her first importation. The shipping of Liverpool and Bristol rivals that of London and Leith, but the shipping all arrive with *clean bills of health from ports not yet contaminated with cholera contagion.*

The *secondary spread of the pestilence* which is now begun will be marked by the appearance of cases at these western ports, as well as some of our inland towns, which are unfortunate enough to receive many infected tramps.

Verbal quibbles about the meaning of contagion are worse than useless. Our great lexicographer defines contagion by the term infection. The terms are synonymous, for he equally defines infection by the word contagion. Contagious matter is either liquid,

as in the small-pox vesicle, or solid, as in the dried pustule, or it may become diffusible in the aqueous vapour of the atmosphere. It then assumes the miasmatic state. The emanations from the bodies of the sick are of this atmospheric character, and consequently become the sport of the winds, or remain hovering like a mist, when the air is stagnant or loaded with moisture. When the temperature favours decomposition or putrefaction, nearly all contagious increase in virulence. Syphilitic contagion appears never to spread atmospherically, though it must decompose, of course, as do all animal poisons. The poison of scarlatina, on the contrary, is highly diffusible; *such appears to be the case with pestilential cholera.*

The contagion of this Asiatic scourge has now for many years been a fruitful topic of controversy in medical fraternities. Among the early practitioners of India who witnessed the first outbreak and successive ravages of this new plague in Hindostan, the analogies of the disease, to the more violent forms of the simple cholera, so accurately described by Sydenham, and ascribed by him to the atmospheric and epidemic conditions of the autumnal season, led them to lose sight of *the specific character of the new disease*, which was at length discovered to be so completely *sui generis*, as to deserve a more diagnostic name than that which they have given to it.

Looking upon it only as a climatorial development of the same disease, in a more aggravated form, they were content to call the one *English*, and the other *Indian*, cholera.

No doubt India had often suffered from epidemic visitations of ordinary cholera, as England and other climates had done. The abundance of the fruit season, and the excessive temperature of the Indian summer, produced the common cholera of milder climates in an endemic form, and they were accustomed, before 1817, to observe occasionally the vomiting, the purging, the cramps, the collapse, and the death of many who were seized.

But the occurrence of the new disease, *during all the seasons of the year*, taking a definite course, with a far more fearful mortality, defying the ordinary therapeutic means with which they were accustomed so successfully to combat its prototype, presenting to accurate investigation some new symptoms of a marked character, at last opened their eyes to that ever recurring enemy which, since 1817, they have had to meet, *in some quarter or other, in every season of the year.* It was as natural for them at first sight to imagine such a peculiar disease free from the principle of contagion, as it would have been, had it been an indigestion or liver complaint. There was no visible eruption of any morbid product on the surface of the body, as in small-pox, or measles, or scarlatina. Many of those who were in close communication with the sick, either entirely escaped, or suffered *but slightly*

the symptom of *diarrhœa*, which they never presumed to call an *attack of cholera*, so that at first sight the conclusion was almost universal that cholera was uncontagious. Kennedy, who so graphically describes the new disease, says, even in 1818, the year after its first appearance in Jessore, "month after month, during the preceding year, fresh accounts reached us of its progress westwards, and the general alarm and horror were excited to the utmost when every hope that the disease might *terminate with each change of season was at last extinct*." The season merely influenced the virulence of the disease, as it influences other diffusible contagions. The morbid material, whatever it was, survived the winter only to break forth with renovated vigour in the warmer weather; and a population of a hundred millions, notorious for their migrations and their festivals, ever presented a sufficient number of victims to be annually sacrificed to this new enemy of the human race. They were not a drunken and dirty people, for their religion was diametrically opposed to such habits, but they are principally vegetable feeders, rice being their chief article of diet, and they live a large portion of their time in the open air.

In examining the question of the contagion of cholera, we must ever bear in mind, that even could it be put to the test of inoculation, which has not hitherto been successfully accomplished, and thus obtain for it the direct demonstration of its infectious property, as we have found in small-pox, that *many cases must arise after it has once appeared in any country which cannot be traced up to any known communication with the infected*. Dr. Gregory, who has paid so much attention to the subject of small-pox, declares that nineteen out of every twenty persons received at the Small-pox Hospital, are unable to discover the source of their infection. They imagine they breed the disease; they attribute it to a chill, or to excessive fatigue, or to getting wet, or to a hundred other very innocent causes, rather than its true one—infection—of which they are unconscious. The difficulty sometimes found in tracing an infectious disease up to its true sources, does no more invalidate the doctrine of contagion than would a hundred undetected larcenies lead us to suppose that they could be committed without the thief.

The analogy of the new disease lately introduced among the sheep of this country, may suggest to us a parity of reasoning respecting the cholera. The very Merino sheep which first brought the "*variola ovina*" into England, have been clearly detected. The disease, however, has now appeared in so many of our counties, that the links in the chain of infection become extremely difficult to trace, and it often *now* arises without any previous communication with infected flocks,—the atmosphere appearing to be the vehicle of the contagion. *Thus it is with cholera.*

When a small island becomes the seat of a new disease, as when Iceland, in 1707, was first seized with the small-pox; or Malta, after an absence of more than a hundred years, with the plague in 1813, or the cholera in 1837, the important question—"whence comest thou?" is put with some probability of a satisfactory answer to the new visitant. The identical ship by which it is imported becomes easy to recognize, and the earlier steps of the invader are tracked with considerable accuracy, until the multiplied secondary or tertiary sources of contagion baffle further inquiry, and the original thread becomes in "wandering mazes lost."

In continental countries it becomes more difficult to bring these inquiries within so small a compass; and in our own island, whose numerous ports are filled with the shipping of all nations, such floating arks of pestilence may, like the Cronstadt vessel lately mentioned by Dr. Simpson, infect the pilots of Newhaven, sail out of port, and baffle for a considerable time the most diligent inquiry. So numerous are the flags that daily and hourly enter our harbours and roadsteads, that supposing cholera to arise from contagious or infectious emanations, we must within the last three months of unrestricted intercourse with Hamburgh, Riga, and Cronstadt, where the cholera had been raging previously, have received many of these foci of contagion; and yet, notwithstanding the "*suppressio veri*," and the "*suggestio falsi*," which have been used pretty freely, there is enough evidence for us to ground a pretty strong case against these northern vessels.

Sailors, it may be, very opportunely eat voraciously of plums and drink sour beer, or some convenient cesspool is at hand in every locality, to bear the blame. The bilge water, too, is another prolific source on ship-board, or some want of cleanliness is perhaps pointed out by some inspector who sees great negligence in the sanitary arrangements on board nearly all the coasters. As for contagion, Dr. Parkes puts on his spectacles and says he never saw it cross the lines at Moulmein or Tenasserim. Mr. Grainger says the medical men of Hamburgh pooh, pooh! at such a silly idea; and that they have very diligently dissected the dead bodies for it, and cannot find it. Alas! that men should ever be employing their external senses and their powers of observation, and should so entirely omit to exercise the reasoning faculty, by which alone invisible agency is proved to exist. Gravitation is not less a property of matter, though it is essentially invisible, and is ever undistinguishable save to the eye of reason. In the hands of Newton, it solved the problems of planetary motion, and the irregularities of celestial bodies were all found, not indeed exceptions, but legitimate consequences of this general law, when deeply investigated.

There cannot be the slightest doubt about the propriety of those sanitary improvements, which have been so strongly recommended, but to assume that

a disease is non-contagious, because cleanliness and ventilation mitigate its severity, and sometimes disarm its concentrated potency, is illogical. A disease cannot be *contingently contagious*, though it may spread or not according to certain contingencies. The theory of a disease being sometimes contagious and sometimes not, is self-contradictory and absurd. Similar kinds of matter always possess similar properties, and the specific virus of the choleric pestilence forms no exception to the general rule.

It is sometimes said that cholera is not contagious, because it is not attended with an eruption like the exanthemata. To this we would reply that all *a priori* reasoning of this kind is scarcely allowable when we have the positive facts to determine the question. Let us however, for a moment, examine the point as if no such positive evidence were within our reach;—as if no basis for inductive reasoning existed;—and as if we were thrown altogether (which is far from being the fact,) upon the mere analogies of other diseases to draw our inferences. “In cholera,” say our Sanitary Commissioners, “no vitiated secretions occur.” All epidemic diseases commonly regarded as contagious are diseases of excitement, during which inordinate actions the fluids of the body become vitiated, and the excretions often so highly offensive, that they appear to possess a septic or putrefactive tendency. “In cholera,” they state further, “there is no power to generate poison, and no activity in the excretory apparatus to throw it off.” Now, it may be true, that in some rare cases of sudden and early collapse, the secretions may appear suspended,—*collapse, however, is not cholera*, it is only one of its occasional symptoms, and it occurs now and then at the onset of other diseases, as in scarlatina and typhus, and may terminate in death or be followed by the stage of reaction and excitement. Some writers, as Dr. Billing, define cholera as a fever, of which collapse is an early and frequent symptom. Others, as Dr. Bell, call it an ague; and Dr. Dickson, with perhaps as much correctness, calls all diseases agues, because they are attended with intermissions and exacerbations. We prefer the view of Dr. Billing; and if cholera be a specific fever, what becomes of the loose statements of our Sanitary Commissioners? If we require morbid secretions, have we not in the premonitory diarrhoea and in the rice-water evacuations, quite sufficient evidence, that in the internal lining membrane of the intestinal canal, there has existed enough of “excitement,” “increased action,” and “morbid secretions,” in abundance? Our Commissioners seem to have forgotten, that the Germans long ago have discovered in the fæcal evacuations the *broken-down epithelial cells* of the small intestines. The debris of these cells, cast off by a species of *internal desquamation*, afford ample evidence of violent excitement, and remind us of those external diseases denominated exanthemata,

such as scarlatina, in which the cuticle so completely desquamates, and becomes sources of contagion.

Henle, in his “Retrospect of Pathology,” published in Müller’s *Archiv.*, 1839, gives an admirable account of the pathological researches of Böhm. A translation of this analysis is published in the *Medical Gazette* of November 22nd, 1839, from which I extract a few passages, recommending those interested in the inquiry to the original document.

“In the contents of the intestines of cholera-patients, Böhm has discovered the debris of the epithelium of the mucous membrane of the digestive canal, and he hence refers the phenomena of the disease to a morbidly accelerated process of desquamation from the membrane, which he has accurately traced through its several stages. The affection of the internal membrane of the digestive canal is not equal in its several parts; the stomach suffers little, and the large intestines least of all; it is the *small intestine, which is for the most part attacked throughout its whole length*.

“After the destruction of the cuticle, and when a raw surface remains, the destruction goes on in the very substance of the mucous membrane. The villi become thinner and weaker by a kind of maceration, their swollen free extremities split up, and assume a fibrous appearance, by the increase of which they are gradually cleft to their bases. The intestines thus affected, in irregular scattered spots, look like an old hide from which the hair is in part worn off. The extremest degree of destruction is found at the end of the ileum, where the Peyerian glands perish, and the mucous membrane is converted into a cracked and broken-up surface; but the whole process is effected with such rapidity, that patients, who in the morning complained of at most an uneasy moving of the intestines, and who die at noon, already present at their *post-mortem* examination a considerable destruction of the mucous membrane. It is the fragments of the epithelium, which, mixed with the effused fluids, form the contents of the intestines. If the latter remain for a certain time at rest in a glass, their microscopic constituents will sink to the bottom. The contents of the intestines appear milky when the *quantity of secretion* is considerable in proportion to that of the elements of the epithelium, and the latter are very minutely divided. They are pus-like, or cream-like, when, on the contrary, the quantity of fluid is small in proportion to that of the solid constituents; flocculent when the epithelial cells are still connected in considerable masses; rice-water-like when similar flocculi float in smaller numbers in a turbid fluid; gruel-like when larger portions of the epithelium (some of a white and others of a greyish-green colour,) are mixed with one another, and connected by a scanty secretion into a mass of a pulpy consistence.”

Böhm has abstained from all conjectures on the nature of the process which he has thus accurately

followed in all its phenomena. But the process by which the epithelium of the intestines is removed, has the greatest analogy to the formation of vesications; and Böhm has himself, in many places, compared the one with the other. The cause of desquamation is a mechanical and passive separation of the cuticle by the exudation, and the exudation is the essential part of the disease. This may be produced in two ways,—either by a primary general alteration of the blood, by which it becomes thinner, or by a local stagnation and change of it by a process which *we name inflammation*. The first is improbable, because the process is *limited to the intestinal canal*, although the inner surface of the lungs and other organs is not less delicately formed. For the second view, the symptoms of the disease and other morbid appearances which Böhm found after death, are all favourable: as for instance, the injection of the vessels which is constantly coincident with the desquamation,—the tinging of the whole substance of the villi with blood,—the presence of fibrinous coagula in the effused fluid,—and the exudation of plastic lymph on the outer surface of the mucous membrane, in the region of the Brunnerian and Peyerian glands. All the secondary symptoms of cholera are explained by the great loss of serum which takes place so rapidly from the walls of the intestines, from the alteration of the blood thereby produced, and from the extended affection of the nerves of the internal surfaces. These circumstances do not act differently from a *burn*, which is attended with blisters over the whole surface of the body.

We think it highly probable that these *morbid cells generate the specific poison of the cholera*; and the fact of a camp thus contaminating those who are within the circle of the fecal evacuations, (*not from ordinary putrefaction and decomposition which does not produce Asiatic cholera*;) re-infecting those who shortly afterwards occupy the same position, connected as it has often been with the additional fact of the cessation of the disease on frequent removals of bodies of men into new and uncontaminated districts, all seem to corroborate the inference we draw from *an undisputed pathological phenomenon*. We are fortified in this view, too, by the acknowledged danger of a residence near the mouths of sewers, when the disease has once made its appearance; and the great fatality and frequency of the disease in those cities where dirty privies are situated within the houses,—as in Paris, where the first, second, third, fourth, fifth, and even sixth floors has a foul nest of contagion of this character, and where the habits of the people are so devoid of cleanliness in this particular. I lived in Paris the year before the cholera broke out; it was then dangerous to walk in many of the narrow streets at night, lest something filthy coming down from an upper story should assail you. As for French privies no Englishman could use them, but willingly paid two *sous* for a “*cabinet d’aisance* a

l’Anglais.” I hope Glasgow does not offer another example of this character, but not having resided there, I am unable to state whether such facts as I witnessed in Paris may not account for the great fatality of cholera in some towns of Scotland.

The French live more upon vegetable diet than the English, and hence, probably, are more susceptible of the malignant form of cholera. Comparative anatomy teaches us that the development of the intestinal tube depends upon the nature of the nourishment. Animals which feed on vegetables require greater powers of assimilation, and have a much larger and longer digestive apparatus than those which are carnivorous. The difference in the length and diameter of the intestinal convolutions of the dog and the horse is immense. We have no doubt that the Hindoo, feeding wholly on rice and vegetables, has more amply-developed *small intestines* than the flesh-eating European, and hence a larger surface becomes exposed to a disease which seems to concentrate its morbid action upon this doubly-worked and highly-sensitive mucous membrane. The soup-fed and water-drinking children at Tooting, approximate in their susceptibilities to that of the Hindoos; their crowded state *concentrated the contagion*, and hence the mortality at which we have all shuddered.

(To be continued.)

SHORT NOTES ON THE OPINIONS AND PRACTICE OF THE LATE JOHN PEARSON, ESQ., F.R.S., ON SYPHILITIC DISEASE.*

By W. S. OKE, M.D., Physician to the Royal South Hants Infirmary.

Dysuria Vesicalis.—This term comprises those diseases of the urinary passages, where the urine is voided with pain and difficulty, in small quantities, and with frequent desire.

1. *Strangury*.—This often arises from the use of acrid aliments and medicines, especially cantharides; and also from exposure to cold after the body has been much heated. When it proceeds from these causes, it may generally be removed by large quantities of diluting drinks,—by opium, soothing enemata, emulsions, &c. When brought on by riding on horseback, a tea-spoonful of the sweet spirit of nitre will often give relief.

It often occurs as the result of ischuria, the bladder becoming as intolerant of the stimulus of the urine as before it was insensible to it. This will generally subside without remedies. In strangury from this cause, after opening the bowels, it is customary to give camphor, the mucilage of gum-arabic, &c., but without much benefit. The best method is to give bark freely,

* Concluded from page 661 of last Volume.

after a purgative, which will generally be found to give relief.

Strangury is not an unfrequent consequence of gonorrhœa, the patient feeling a frequent inclination to void his urine, and passing it with uneasiness. In this case the infusion of *uva ursi*, hemlock, and bark, may be given with advantage, but the remedy mostly to be depended upon is opium, combined with small doses of the diacetate of lead.

2. *Irritability of the Bladder*.—This may arise from three causes:—1st. From simple increased mobility of the muscular fibres, producing painful efforts to void the urine. To relieve an irritable bladder from this cause, the *uva ursi* may be given; and relief will often be observed by passing a bougie a few inches into the urethra, or a very fine bougie into the bladder. Should these means not succeed, a blister may be applied to the sacrum, and the catheter occasionally introduced. Half a grain of the lytta powder will often be found useful, taken three times a-day. 2nd. Irritability of the bladder may be the result of a suppressed gonorrhœal discharge, or metastatic gout. In the former case the indication will be to bring back the urethral discharge, which will best be effected by introducing a bougie into the urethra, smeared, if necessary, with some irritating matter. Should this means fail of such an effect, benefit will probably be derived by blistering the glans penis, and producing an external discharge. When irritability of the bladder takes place from misplaced gout, there is a discharge from the urethra, more or less, like gleet; and in almost all cases of strangury, flocculent matter will be found floating in the urine. Here the object is to bring on a fit of the gout, but in what way this is to be done it is not easy to explain; and the most probable means of producing it, such as plunges into cold water, cannot be adopted with safety. 3rd. Irritable bladder may arise from an abrasion of the mucous surface. In this case thickening and ulceration are to be apprehended, and when this result has taken place, a mucous or puriform fluid is discharged with the urine. Large doses of the balsam of copaiba—as a drachm three times a-day—will be attended with most benefit; and should any blood be mixed with the urine, then, in addition to the copaiba, a glyster of the *Infusum Lini* and laudanum may be thrown up the rectum; but when thickening has taken place, medicines will only alleviate pain, and the best of them all is opium.

Hæmaturia.—Hæmaturia occasionally arises from general or partial plethora, particularly from a turgid state of the veins about the neck of the bladder, when the patient voids a pint or more of blood after exercise, and without pain. It sometimes occurs from the sudden contraction of the bladder upon the end of the catheter, when introduced to draw off the urine. At other times it is the result of inflammation of the bladder, where

previous disease existed, and is attended with a full pulse, white tongue, and all the ordinary symptoms of inflammation.

Men advanced in years have sometimes bleeding from this part, amounting to one or two drachms in quantity at a time, which is often connected with a diseased prostate gland.

Children also are occasionally subject to hæmaturia, which may be considered as analogous to bleeding from the nasal passages. This case will generally yield to aperients and sulphate of zinc.

When hæmaturia arises from an irritable bladder, associated with dyspepsia, it is not usually dangerous; but if it arise from a fungus in the bladder, or from a diseased state of the prostate gland, the case is beyond the reach of art. When it is caused by inflammation, blood should be taken from the arm, and from the neighbourhood of the bladder; rest and low diet are to be observed; cold should be applied to the pubes and perineum; and castor oil, nitre, and mucilaginous drinks are to be prescribed. After the subsidence of the inflammation, tonics will be found beneficial.

When hæmaturia is apparently derived from a full habit, and is unattended with pain, it may be presumed to arise from plethora. Here general and local bleeding may be tried, but in such cases little can be done. The bladder is very intractable, and the hæmorrhage ceases when it chokes. When there is much languor, small doses of the *Oleum Terebinthinæ* may be given, and perhaps with benefit; but this remedy is not always to be recommended.

[The following remarkable case of hæmaturia came under my notice about four years ago, and it corresponds with the character of plethoric hæmaturia, above alluded to by Mr. Pearson:—

A lady, aged 67, of stout form, full habit, and of gouty constitution, from successive mental excitement became subject to rushings of blood to the back part of the head, and to palpitations of the heart, accompanied with serous infiltration into the peritoneal cavity, and œdematous swelling of the lower limbs. These symptoms continued for a considerable length of time, and gave rise to, and were eventually relieved by, profuse hæmaturia, recurring at irregular intervals from one to six weeks. The blood was of a venous colour, and sometimes passed in clots, which threatened to obstruct the urethra. This state of things had gone on for three years, and, although she looked pallid from such repeated losses of blood, and was of course weakened by them, still, after the hæmaturia ceased, she always felt relieved of a sense of fulness of the abdomen, and of pain, weight, and stiffness of the loins, which usually preceded it. The bleeding probably issued from the renal function; but as she never complained of any spasmodic pain of the lumbar region, and had never passed any calculous matter, it may be fairly inferred that the bleeding was the result of a plethoric condition of the portal system, rather than of calculi in the pelvic cavities of the kidneys. She had consulted several

eminent physicians without any decided benefit. The hæmorrhage ceased and recurred according (apparently) to the state of the vascular system. The urine, when the hæmaturia was absent, was not albuminous.]

Dysuria Urethralis.—1. *From Indurated Swellings about the Veru-montanum.*—In this case the canal is not much diminished, but the stream of urine is small and voided with difficulty; a kind of gleet is always present, which does not yield to common remedies, and spasm is caused by passing a bougie; there is also uneasiness in the perineum, ardor urinæ, and impatience to void it. The most certain sign of this disease is a bloody state of the semen. The cure must be attempted by the proper use of bougies, and by producing a discharge in the locality of the induration, so as to remove, if possible, the callosities.

2. *From Stricture.*—Strictures of the urethra may be divided into three kinds. 1. Simple contraction. 2. Contraction, with spasmodic action. 3. Purely spasmodic action.

Strictures occur in almost every part of the urethra but more frequently behind the bulb. Strictures sometimes produce a suppression of the secretion of urine, so that, perhaps, the patient makes water once only in sixteen or eighteen hours. When the stricture has been dilated, the secretion is considerably augmented and the stream is increased.

During the existence of a stricture the urine is divided in a small stream, has a forked appearance, dividing into two or three streams, or is flattened transversely, or twisted like a corkscrew.

Strictures are also frequently followed by retention of urine, from any irregularity, such as drinking spirits, and using long continued or violent exercise.

The existence of stricture can only be ascertained by the introduction of a bougie, and in performing this operation the young surgeon should be careful he does not mistake one of the lacunæ of the urethra for stricture, a mistake into which he may be apt to fall.

The existence of urethral contraction does not prove that the patient has ever had any venereal complaint, since it may occur where there has been no gonorrhœa.

There are three methods of curing strictures; first, by incision; second, by caustic; and, third, by dilatation. The method of curing primary stricture by incision is a very dangerous, and has proved a fatal, operation, one indeed which can scarcely be found necessary. The method of cure by caustic is of ancient use, and was long employed before the advantages of the mechanical method were understood. In simple spasm, caustic, judiciously applied, will relieve much sooner than a simple bougie, but it must be admitted that it occasionally produces violent rigors, resembling those of ague; dangerous hæmorrhage, which has brought the patient to the brink of the grave; severe irritation of the urethra, and extensive induration of

the canal, as if a great part of it had been destroyed, producing a lengthened and impenetrable stricture; indeed the inconvenience and dangers are frequently so great, that no persons should make use of caustic in the treatment of stricture unless they are acquainted with the advantages and disadvantages resulting from its employment; besides, strictures may be treated sooner without, than with caustic, and patients are not less liable to a relapse after the use of caustic, than when cured by the simple bougie.

Mode of using Bougies.—With regard to composition, bougies ought to have a smooth and mild surface, with a due degree of stiffness.

Having been imbued with oil, the bougie is to be passed slowly and with gentleness, at the same time drawing forward the urethral canal. It ought never to be suffered to remain in longer than an hour, indeed half an hour will often be found long enough. The introduction should not be repeated oftener than every other day, and great care should be taken not to inflame the urethral membrane, lest such a result may delay the repetition for a week or more.

It is not uncommon for the use of the bougie, at the commencement, to occasion rigors, and some degree of ardor urinæ, but these effects will generally subside after it has been introduced several times.

If a swelling of the testicle supervene, the bougie must at once be discontinued; or if an abscess in the perineum take place, or in the cellular membrane, between the scrotum and thigh, with inflamed and tumefied absorbents, the bougie will no longer be admissible, and the patient must be kept quiet, and a poultice applied; sitting over the steam of hot water will also be of use in this case. A swelling of the prepuce to a considerable degree, and irritability of the bladder, are sometimes also produced by the use of bougies, which symptoms are to be treated with the ordinary remedies. These untoward results shew that the surgeon ought not to be in too great haste to cure a stricture.

When the bougie is left in the urethra, care should be taken to secure it lest it slip into the bladder. This sometimes happens, and when it does occur, the urethra is to be grasped firmly in perineo, and the penis retracted over the bougie.

Bougies at their distal ends should be rather conical, so as to act on the stricture, but if the contraction be so great as only to admit the passing of a very small bougie, it should terminate by a round point. Those which bend readily are more advantageous in some strictures, as they follow with the windings of the canal which have been produced by the disease.

Bougies must be regularly used, till the whole canal is open, and this may be accomplished in from six to twelve weeks; afterwards they must be introduced occasionally,—as once a fortnight, then once a month, and lastly, once in three months.

In spasmodic stricture, large bougies with obtuse ends will be most useful. When the meatus urinæ is contracted, the continued distension from a uniformly large bougie gives considerable pain, and may occasion hæmorrhage, it therefore is convenient in such a case to have the end of the bougie larger than its middle, and thus the constant distension of the contracted orifice will be avoided. Great inconvenience certainly results from a small meatus, but it will be better to be content with passing a bougie the size of the orifice, than to enlarge by incision.

A sound will sometimes pass where a bougie will not, but if much force be used with either instrument, retention of urine may be the result.

When by the passing of a bougie water is made to escape from the bladder, as in ordinary cases of retention, the bladder is not always able to evacuate itself wholly by the first effect, and then it becomes necessary, after waiting a quarter of an hour, to introduce it again, in order to produce another contraction.

When strictures occur at an inch and a half to two inches from the meatus, they are very troublesome, and it is in these that contraction of the meatus more commonly occurs.

Hæmorrhage rarely happens except from violence, or from the urethra contracting firmly upon the bougie. In some persons there is great tenderness of the urethra, so much so, that it cannot bear any plaster bougie, but finds no inconvenience from a metallic one; some, indeed, cannot bear wax composition in any form.

When a bougie is unskilfully managed, a false passage may be made through the urethra into the cellular membrane. This may be suspected when there is no alleviation from a long continued use of bougies.

If the stricture be so complete as not to admit the finest bougie, an endeavour must be made to induce suppuration of the part by covering the end of a large bougie with the Unguentum Hydrargyri Nitratis, and pressing it against the walls of the stricture.

When the stricture is complicated with spasm, great obstruction will probably be found at first, but after gently pressing for some time against it with the bougie, it will suddenly pass into the bladder, or the spasm may often be relieved by gently irritating the urethra at its extreme part. If the spasm should not yield to these simple means, it will be advisable to apply a blister to the perineum once or twice before the bougie is resumed.

In the purely spasmodic stricture, a slight touch of the caustic will speedily remove the spasm. If this be not used, a very large bougie, or a cold sound, or a blister to the perineum, may be employed with advantage.

In the treatment of stricture, too much ought not to be attempted at once, although some will bear the introduction every other day, others will only bear it every third day, and it will also be prudent not to

stretch the urethra too much at any one time. In this place Mr. Pearson relates the following interesting case:—"A patient in the Lock Hospital had a stricture two inches from the meatus, through which the smallest probe could not be passed; it seemed a complete *cul de sac*, and the urine could only be passed in small drops, and with great pain. I introduced a director, and laid open one inch of the urethra to the point where the director terminated. I then dissected down to the contracted part of the canal, and found it in a very indurated state; half an inch beyond the contraction the urethra was perfectly sound. A catheter was kept in the bladder, and the wound healed in a month, after which a bougie was passed every two days."

Fistula in Perineo.—When a person has laboured long under strictures, as the bladder meets with unnatural resistance, some portion of the urethra between the bladder and the stricture becomes dilated and forms a pouch for the urine. The urethra at length in some parts of the pouch gives way, and if the orifice be small the urine passes into the cellular substance by drops; a tumour is then formed, partly of pus and partly of urine, which does not always burst externally. The abscess may rupture as high as the buttocks, and even at the lower part of the abdomen. At other times there may be eight or ten different openings, and an immense quantity of pus discharged.

In every case of simple fistula in perineo, the employment of fomentations, poultices, and bougies, will generally be successful. The cure of the strictures will in most cases be the cure of the fistula.

When the stricture is so complete as not to leave the urethra open, it must be perforated; and as there is not always the advantage of having a staff, the operation is sometimes attended with difficulty.

In cases where several sinuses are found, they must be laid open, their edges scarified, and the indurated parts removed; it is absolutely necessary to touch the staff by a probe introduced through the incision, for merely laying open the integuments is not sufficient. Where no staff can be used the success of the operation is uncertain.

Sometimes fistula is caused by laceration from an accident. The patient makes water into the scrotum, and if a catheter is introduced into the urethra, it will pass through the laceration. In this case, first make a free incision into the perineum to remove the blood and urine; and when suppuration has taken place, introduce a soft bougie into the bladder. After the fistula has been laid open down to the urethra, a catheter is sometimes found so irritating, that it has been deemed advisable to lay it aside.

Where the parts are brought nearly into a healthy state, the flexible elastic catheter may be used; but if they are much diseased, the plan will be productive of little advantage. The object is to bring on suppuration

and healthy granulations, and when the catheter is introduced, it ought but seldom to be left in the bladder, unless the difficulty of introducing it is very great. Passing a bougie every day and keeping it in for a few minutes, will do more good; for an attempt to pass the catheter into the bladder will fail, unless the course of the urethra can be found; in all cases, therefore, it will be prudent first to give a fair trial to the bougie before the catheter is used.

There are some cases of stricture in which no instrument can be passed into the bladder: fistulæ, under such circumstances, are advantageous as a salutary effort of nature to save the life of the patient.

Enuresis — Involuntary Flux of Urine.—*Enuresis puerpera.*—When gangrene of the bladder is produced by long continued pressure, and a part of it sloughs, the unfortunate patient becomes subject to an involuntary discharge of urine. Sometimes the inner surface of the urethra is studded with minute calculi, which may be detected by introducing a catheter into the bladder and the finger into the vagina.

There is no particular remedy for this disease. Injections may be used to keep the vagina clean and wash away the lithic deposits. The patient may be rendered more comfortable by putting a portion of soft sponge into the orifice and withdrawing it three or four times a day.

Enuresis paralyticorum. This species arises from diminished power of the sphincter vesicæ, the detrusor power remaining unimpaired. In this case there are two modes of alleviation, one by an instrument called the "sphincter urethræ," which will be found very inconvenient; the other by a bladder being fixed to the penis, which most patients prefer.

Incontinence of urine will often be produced by stricture, especially when near the neck of the bladder; for if obstacles to the exit of the urine are long continued, the parts become overstretched and hardened, so that the sphincter of the bladder at length loses the power of contraction.

Enuresis infantum may arise from too great a mobility of the muscular fibres of the bladder, or a diminished power of its sphincter. In this disease, the indication is to increase the tone of the part. Taking large quantities of liquids should be avoided, and the remedies to be employed are the sulphate of zinc, cold bathing, and blisters to the perineum or sacrum. The tincture of cantharides may also be given advantageously, beginning with the dose of twenty drops for a child seven years old, and increasing it till strangury is produced; till this is effected little good will be experienced. The patient should feel a sense of heat and uneasiness, and frequent desire to make water. If the pain be violent the dose may be lessened, and continued in such a quantity as can be borne without inconvenience. Electricity is sometimes of use.

I have now brought these papers to a close. One more might have been added on syphiloid disease, but as I can discover nothing in the manuscript before me that could throw any light on this morbid complication, either in a pathological or therapeutic point of view, (for, in Mr. Pearson's time, the curative efficacy of the iodide of potassium was not known,) I have deemed it best to omit it, and I am the more justified in doing so after the recent publication of M. Ricord's valuable lectures on syphilitic disease in the pages of the *Lancet*, which comprise all that is known on this subject.

I am but too conscious of the very imperfect character of the notes which have been so indulgently recorded in this Journal, and I sincerely hope, if any autograph of the late Mr. Pearson on lues remain in the possession of his relatives, it will one day be given in a complete form to the public. Such a publication could not fail to become a standard work on this important subject, and at the same time it would be carrying out his declared intention.

In justice to the high professional reputation of the late Mr. Pearson, I think it right to add that he was the first to describe the symptoms and treatment of those forms of disease which he has denominated "erethismus" and "eczema mercuriale," and that he was also the first to recommend "free exposure to air" in cases of excessive salivation.

It might probably appear, *primâ facie*, that his mercurial treatment was unnecessarily severe; but when we find M. Ricord (the most experienced surgeon in lues of the present day,) stating it as his opinion that the syphilitic diathesis can hardly be eradicated, we ought not to be surprised that Mr. Pearson should have insisted on a decided and protracted adhibition of mercury as the only antidote to the true syphilitic poison.

Southampton, December 13, 1848.

A CASE OF INCOMPLETE REDUCTION "EN MASSE" OF AN INGUINAL RUPTURE;

WITH THE SUBSEQUENT TREATMENT, AND APPEARANCES OF THE PARTS POST MORTEM.

By JAMES REID, Esq.,

Surgeon to the Kent and Canterbury Hospital.

The reduction of a hernia in a mass with its investing peritoneal covering, by the efforts used in applying the taxis, and the appropriate mode of treatment, has, until the last few years, rested almost entirely upon the authority of foreign surgeons.

Mr. Luke was the first, I believe, in this country, to make the occurrence the subject of a particular treatise.* Since his excellent paper, founded on the

* Previously to this, cases of the accident had been noticed by Sir C. Bell, Messrs. Green and Callaway, and Mr. Bransby Cooper; but Mr. Luke was the first British surgeon who deduced the line of practice to be adopted.

experience of five cases, was read before the Medico-Chirurgical Society, and published in their "Transactions," notices of three other cases have appeared in the English journals. The hitherto supposed rarity of the accident has therefore much diminished, and the influence that the probability of its occurrence should exert, during the investigation of an obscure case in which symptoms of strangulation exist, has become more recognized. Under present circumstances, however, every additional case may be viewed with interest, and may assist in confirming or elucidating the information already obtained upon the subject. It is with this view that I am induced to publish the following case of incomplete reduction "*en masse*."

J. H—, a strong active old man, aged 75, was admitted under my care, into the Kent and Canterbury Hospital, with symptoms of strangulated hernia. He had been subject to double inguinal rupture, partly occupying the scrotum, for which he had worn a truss forty years; and more recently to a protrusion, the size of a walnut, at the navel. The right inguinal rupture had appeared some few years after the left, and had troubled him most, having on one occasion become incarcerated for several days, occasioning constipation and vomiting, and being at length reduced with difficulty. Two days previous to his admission into the hospital, he exerted himself more than usual in spearing for eels; feeling afterwards indisposed, he went to bed sooner than usual, and was soon attacked with severe pain in the abdomen, followed by vomiting. He then discovered that the rupture had descended, and made ineffectual attempts to reduce it. The next day he renewed the efforts, applying for that purpose a hot tile, and making pressure upon it. After an attempt continued for some time, the swelling was reduced in size, and he considered that he had returned it, but the symptoms still continued. A medical man was now sent for, who detected a small swelling in the situation of the inguinal canal; an attempt was made to reduce it, and purgatives were administered.

He was admitted into the hospital forty-eight hours after the occurrence of the first symptoms. The countenance was anxious; there was constant vomiting, accompanied by hiccough; the matter thrown up was the contents of the small intestine; the abdomen was distended, but not tender, except in the immediate neighbourhood of the right inguinal region; there had been no action of the bowels for forty-eight hours. Tongue stained by the matter vomited; pulse of natural frequency, full, intermitting; the radial artery felt ossified. About the situation of the right internal abdominal ring, there was a small diffused swelling, (better perhaps described as a fullness of the part,) so ill-defined that it was said, at first, there was no protrusion; however, on comparing it with the opposite side, and pressing in the fingers around it, the tumour was more readily detected. Pressure upon the swelling produced pain, and caused it to recede; but it returned immediately upon the pressure being relinquished. A lump, feeling like a loose sac containing omentum, occupied and extended from the external ring.

The taxis in the warm bath, a turpentine injection, &c., producing no change, an operation was determined upon. An incision was made opposite the internal ring directly over the swelling, and continued parallel to the inguinal canal. The tendon of the external oblique, the fibres of the internal oblique and transversalis, each, in distinct layers, were divided, and a hernial tumour, the size of a large walnut, was exposed in the upper part of the inguinal canal. A portion of small intestine, of a dark colour, but reserving its natural lustre, and a small quantity of dirty fluid, were found in the protruded sac. This portion of the sac was but a small part of the whole; the remainder was situated within the abdomen, so that it required the full length of the index finger (a middle sized one,) to reach the seat of stricture—the neck of the sac. It was necessary before dividing the stricture, to obtain more freedom by incising the lower edge of the abdominal muscles in a direction across their fibres, and, in order to prevent the neck of the sac receding from the finger, to have it held by the divided edge. The nail of the fore-finger was then, with difficulty, insinuated between the intestine and the stricture, and the latter was divided. Although the finger freely entered the abdomen through the neck of the sac, some obstruction opposed the return of the intestine. A resisting band was felt, situated to the inner side of the neck of the sac, between which, and the abdominal parietes, the intestine was pressed, and could be felt passing towards the mesial line beyond the reach of a finger; it was dislodged from this situation and pushed back into the abdomen. The wound was closed, and a bandage applied. The further details of the progress of the case until the patient's death are briefly these:—

No immediate relief was afforded by the operation; partial quiet and alleviation of symptoms were obtained by an opiate administered directly after; the vomiting continued and constipation remained. No satisfactory action of the bowels was obtained by the free exhibition of enemata, thrown up with the long elastic tube introduced to its full extent. Symptoms of peritonitis were established (in spite of remedies,) twenty-four hours after the operation, and in thirty-six hours, evidences of failing vitality appeared; gangrene of the posterior part of the scrotum was discovered, and in the course of twelve hours it spread over the scrotum, penis, lower part of the abdomen, and upper part of the thighs. The patient died in rather more than forty-eight hours after the operation.

Post-mortem examination thirty-six hours after death.—The gangrenous integument was distended with gas. The layer of adipose tissue was thick; the edges of the wound not adhering. There were evidences of general peritonitis, which were most marked in the right inguinal region, where the convolutions were glued together by recently effused lymph. The portion of intestine that had been strangulated, consisting of nearly a foot of the upper part of the ileum, was dark coloured, almost black, covered with patches of recently effused lymph, puckered up in the position it must have assumed in the sac, and deeply marked by the stricture, having an additional depression, partly encircling it below the indenture. The position and

relation of the sac will perhaps be better understood by describing it as forming a double pouch, with a common neck and opening; a smaller pouch, about one-fifth of the whole, partly within the abdomen, and partly protruding through the internal ring, and a second and larger pouch, placed nearly at right angles to the former, and extending from the inner side of the internal ring between the peritoneum and abdominal parietes. The cord of the obliterated hypogastric artery had been separated from its natural position on the inner side of the internal ring by the interposition of the larger pouch. It was this which formed the resisting band felt during the operation, and which had caused the second mark upon the portion of intestine that had been strangulated. The sac was readily drawn out from its double position, and then formed a simple bag. The outer side of the neck of the sac was only slightly separated from its connection with the abdominal parietes. The substance which had been felt at the external ring proved to be a mass of fat, connected by a long pedicle, extending up the inguinal canal to the exterior of the protruded portion of the sac.

Mr. Luke, in his observations, says "that the firmness of the adhesions of the parts in which a hernia is imbedded bears no proportion to the duration of the hernial protrusion." This remark is of great importance in relation to the efforts that it is safe to make in reducing a hernia by the taxis, both as regards the degree of force to be used, and the period to which it may extend. The evidence furnished by the present case is not very satisfactory on this point, as I could not obtain from the patient a very clear detail of what had previously occurred. As far as I could ascertain, the force used was not sufficient to cause much pain, the reduction of the swelling was perceived by a gradual diminution in its size, not by any sudden decrease. There was no appearance of injury or bruising of the integuments in the neighbourhood of the swelling when he was admitted into the hospital, and the intestine also was free from ecchymosis. On the whole, I am inclined to the opinion that the reduction was effected *more* by the continual employment of a degree of force, not injurious perhaps in itself, than by any one or more undue violent efforts.

My first conclusion with regard to the nature of the present case was, that a scrotal rupture had been partly reduced, a portion of intestine remaining in the inguinal canal, constricted in some manner at the external ring. This opinion was founded on the evidence of the indefinite swelling, the form a protrusion assumes when small and confined to the inguinal canal, and the pressure at the external ring of what I thought was a hernial sac. The ready yielding of the tumour and its reappearance raised a difficulty to such a diagnosis, and a suspicion of the real nature of the case was then entertained; but the supposed sac at the external ring was an obstacle to such a view of the matter. The clear indication, under existing circumstances, was to cut down on the swelling in the canal, and explore the mystery. The formation of fat about the sacs of old herniæ is mentioned by some authors on hernia.

I have, since this case occurred, noticed a similar

mass of fat appended to an old scrotal hernia that became the subject of a *post-mortem* examination; it was uniformly attached to the sac, though easily separable, and might have been left behind in the reduction of the sac, in the manner that I conjecture the mass in the present instance to have been. More recently, in operating upon a strangulated inguinal rupture, which had existed many years, and been operated on before, after I had divided a very thick layer of fascia, a mass was exposed, resembling at first sight, omentum covered with a thin sac; it proved to be a layer of fat about 1-3rd of an inch thick, connected with the sac which was situated beneath it.

Mr. Luke, in speaking of the facts connected with reduction in mass, and the conclusions to be drawn from them, remarks "that the presence of a sac, even without hernial contents, causes an abdominal fullness in the part, easily ascertained by examination. The absence of such fullness in a part where hernia is known to have previously descended, necessarily leads to the conclusion that the sac upon which it depended has been displaced, and probably returned, together with the hernia. The sac in inguinal hernia below the external ring, becomes united with the spermatic cord, whereby the latter is usually rendered indistinct and obscure. The absence of that indistinctness and obscurity implies the removal of the cause which previously produced them, and, therefore, that the sac has been displaced. The *continuance* of the indistinctness or obscurity leads to a directly *contrary conclusion*."

The present case shows that the conclusion to be drawn with regard to the presence of the sac, from the existence of a substance feeling like omentum in the situation recently occupied by a hernial protrusion, suspected to have been reduced in mass, should be received with some reservation.

Unconfirmed by other evidence, it cannot be viewed as a certain proof. In addition to this, the existence of depositions of fat in the cord often placed at the external ring, cysts of the cord, and varicocele, would cause a fullness and obscurity about it, which could not be distinguished from that occasioned by the sac, with or without some portion of its contents. The only effect, perhaps, of this uncertainty on practice in such cases would be to afford additional reason for an exploratory operation. The direction which the returned bowel with its investing sac took, to the inner side of the internal ring, is not that which appears generally to have been observed in inguinal hernia,—viz., below the level of the internal ring towards the cavity of the pelvis, or else towards the outer side of the ring. The incomplete reduction of the hernia is in accordance with the results of the experiments made by Jules Cloquet on the dead subject,—that "in external inguinal hernia, the reduction is generally incomplete, and the swelling re-appears as soon as the efforts at reduction are discontinued." I cannot help thinking that, in this instance, the obliterated hypogastric cord had some share in causing the small portion of the rupture to re-appear when apparently reduced, and preventing the complete reduction of the whole. By the approximation of the internal ring, from the long continuance of

the rupture, towards the obliterated artery, and by the interposition of the sac and intestine between the parietes of the abdomen and the peritoneum, (the neck of the sac retaining its connections externally,) the inner edge of the neck and the obliterated artery would be forced in a direction backwards and somewhat outwards, so as to bring the latter more nearly opposite the internal ring. Its resistance, added to that afforded by the connection of the peritoneum with the walls of the abdomen, would then form an obstacle to the complete reduction. Be that as it may, the cord of the vessel exercised considerable pressure, much more than might, *a priori*, have been anticipated. The difficulty in returning the intestine after the neck of the sac had been divided, and the mark discovered about the portion of bowel that must have occupied the large pouch, sufficiently show this. The manner in which the reduced portion of rupture was girt between the hypogastric cord and the abdominal parietes would have prevented the reprotrusion of that part by the efforts of coughing and straining, as have been recommended, the effect of such attempts being to cause the cord to press more tightly upon the part it constricted. The depth from the surface at which the stricture was placed, and the obstacle the hypogastric cord occasioned to the return of the intestine, furnished the only difficulties in the operation. The return of the intestine might have been facilitated by dividing this cord if it could have been recognized; but then, it should be remembered that it is sometimes pervious by a narrow canal conveying blood for the supply of superior vesical arteries, and a troublesome, perhaps serious hæmorrhage, might have resulted. The continuance of the symptoms of strangulation after the operation was due to the portion of bowel not recovering itself after it was replaced.

Canterbury, Nov. 7, 1848.

CASE OF SUDDEN DEATH, CONNECTED WITH PREGNANCY: PHLEBITIS AND DUODENITIS.

By R. F. GEORGE, Esq., Surgeon to the General Hospital, Bath.

(Read at the Quarterly Meeting of the Bath and Bristol Branch of the Provincial Medical and Surgical Association, September, 1848.)

I am induced to bring before this meeting a brief statement of a case which fell under my observation in the early part of last year, on account of its bearings both upon pathology and forensic medicine.

On the 6th of March, 1847, I was requested to see a stout girl from the country, between 15 and 16 years of age, who, I was informed, had been suffering for the last three months from a painful swelling of the left leg. The disease commenced with acute pain in the calf, followed quickly by a firm colourless tumefaction of the whole limb up to the knee. The catamenia had been suspended for four months, but there was no

sickness, no loss of appetite or strength, slight excitement of the circulation, and little apparently amiss in the general health beyond the interruption of the menses and a sluggish state of the bowels. She had a childish horror of medicine, and had therefore imperfectly attended to the directions of her medical adviser, and had rejected the various nostrums which her maternal friends recommended for the restoration of her periodical function. I further learnt, that about six weeks before she came to Bath, after the application of some leeches to the lower part of the leg, and other remedies, the swelling of the limb rather lessened, but that in the night she was attacked with intense pain in the region of the heart, with anxiety, and coldness, which symptoms, under the use of stimuli, passed off, and immediately afterwards the leg returned to its former state of tumefaction. From the character of the swelling, and its history, there could be no doubt of its being the result of inflammation of the saphæna vein, though the cause of that phlebitis was obscure.

I ordered the application of leeches to the calf, with rest, and some aperient medicine, and two days later, finding her easier, I directed their repetition, which removed the pain and swelling, and in three days the patient was able to walk without inconvenience; but on the eighth day she was attacked with violent pain of the same character in the right calf, which the prompt use of leeches relieved in a few hours, and during the remaining four days of her life she moved about with ease. On the day of her death she appeared in good health and spirits, made a hearty dinner of beef, vegetables and porter, with the family, at one o'clock, and remained in the same room where she had partaken of that meal until three. Immediately that she quitted the apartment she began to groan, complained of agony at the pit of the stomach, became faint and vomited, and in three quarters of an hour breathed her last.

I reached the house about half an hour after her death, and hearing the history, desired that a vessel containing a large quantity of the matter vomited, consisting of partially digested food, of a brown colour, and strongly smelling of beer, should be set aside for future examination, a direction which, through the stupidity of the nurse, was not attended to.

Examination twenty-four hours after death:—Body well formed and very fat; complexion muddy; breasts developed with dark brown areolæ; legs still rather swollen and hard; no indurated cord or knot perceptible in the course of the saphenæ; a thick layer of fat deposited between the skin and muscles; blood in the superficial veins extremely fluid. The lungs were healthy, a small quantity of serum being collected in the cavities of the pleura, but not more than would be caused by infiltration. Heart small and rather pale, its right side filled with fluid blood, and a small quantity of colourless serum was found in the pericardium. The mouth and fauces, as well as the œsophagus, presented a healthy appearance throughout. The stomach, and three feet of small intestine, were removed for future examination. The rest of the intestinal tube, and other abdominal viscera, were in a normal

condition; the bladder was free from inflammation, and contained a small quantity of urine. The uterus was emerging from the pelvis; its fundus and upper surface were marked by broad streaks of inflamed veins; its interior was healthy, and contained a male fœtus of about four months. The ovaries were healthy, and there was no effusion into the abdomen or pelvis. The left vena saphena was dissected out from the calf upwards; it was throughout its course red and thickened, and its calibre filled up with a plug of adherent fibrin.

In making the above examination I was assisted by my friend Mr. Soden, and at its conclusion we carried the stomach and the intestine to Mr. Bartrum, by whom, conjointly with Dr. Davies, a most careful chemical analysis of the contents of the stomach was conducted, and at whose house a close investigation of the parts was made on the next day, of which the following is a summary:—

The intestine beginning from the pylorus was three feet in length; it was spread upon a clean board, and laid open through its whole extent; it was generally empty, and the greater part appeared natural in colour. A portion of the bowel, for about nine inches in extent, commencing at the pylorus, was in a state of minute punctiform injection, gradually increasing in intensity; the part included between the fifth and eighth inches, being that in which the depth of colour was greatest, from thence it gradually abated until the redness was lost in healthy structure at about the fifteenth inch from the pylorus. From this point downwards the intestine presented such an appearance as is usual during the time digestion is going on.

Stomach—Contents:—The stomach contained five fluid-ounces of partially digested food, mixed with mucus, of a dark brown colour, smelling strongly of malt liquor; the whole lining membrane of the stomach was spread over with a thick and pretty uniform layer of tenacious mucus; commencing within half an inch of the cardiac orifice, and extending over a space of four square inches, the mucous membrane presented the appearance of acute inflammation, consisting in minute punctiform injection, of a dark red colour; from this point, until within three inches of the pylorus, the mucous membrane was partly inflamed and partly healthy, there being rather an extensive patch of injected membrane about the centre of the viscus. At the point named,—viz., three inches from the pylorus, the mucous membrane was again minutely injected, the colour being more florid than that at the cardiac extremity, and became continuous with the condition already described in the duodenum.

Dr. Davies and Mr. Bartrum, after devoting a considerable time to the analysis of the contents of the stomach, were unable to detect a trace of any vegetable or mineral poison. Their examination was directed to prussic and oxalic acids, arsenic, and bichloride of mercury, besides savine and local irritants, none of which were found.* If we may rely on the results of their varied

experiments, (and, from the care used in conducting them, they are fully entitled to confidence,) the swallowing of poison must be dismissed from our consideration, as a cause of the inflammation of the stomach and duodenum which proved so rapidly fatal. The origin of this destructive inflammation becomes then a question of peculiar interest, taken in conjunction with the uterine phlebitis which, from the history of the case, there is reason to suspect had, more or less, existed during many weeks. The duration of the duodenal inflammation is also a subject of interesting speculation, as there were no symptoms indicating its presence until three-quarters of an hour before death, and yet it is difficult to believe that so much organic alteration as was apparent upon the *post-mortem* examination, could be developed in so short a time.

PROVINCIAL Medical & Surgical Journal.

WEDNESDAY, JANUARY 24, 1849.

It is a singular anomaly that, with a numerous body of educated and extensively-qualified gentlemen, very many of whom are individually held in the highest estimation by the public, and to the exertions of whom, as a body, both the Government and the community stand confessedly deeply indebted, several public offices in the State, which can alone be properly filled by members of the medical profession, should be conferred upon individuals of other professions, or of no profession at all, and whose previous education and habits of life, in many instances, absolutely unfit them for the discharge of duties of this description. To refer again to the present President of the Board of Health, as a most illustrious example of the anomaly:—What can be more absurd, than to find a Peer of the realm, belonging to one of the highest families of the kingdom, an hereditary legislator, discharging the functions of chief of the Medical and Sanitary Departments of this kingdom, almost even without the assistance of any medical person, at a time, too, when a malignant and fearfully fatal pestilence threatens the entire country?

Let us not be misunderstood here, in supposing to infer that the noble lord is descending from his high estate in thus taking office with a view to the conservation of the public health. We have too high a sense of the real position of that profession to which we have the privilege of belonging, to deem it any degradation to the highest in the land, really to know and to

* The substances sought for in the analysis of the contents of the stomach were prussic acid, bichloride of mercury, arsenic, and oxalic acid, not a trace of any of which could be discovered by Dr. Davies or Mr. Bartrum.

practice it, should circumstances render it necessary for them to do so. Nevertheless, it is not the special calling of our hereditary legislators to attend the bed-side of the sick and the dying, and professionally to administer to their wants; neither are they fitted by long previous study for such duties, important and responsible as they are. Had the Noble Peer, indeed, undergone such a course of study, and fitted himself for such duties, there could have been no objection to meeting Dr. the Earl of Carlisle, at the bed-side of the sick, nor to Dr. the Earl of Carlisle, presiding or assisting at a Board of Health; nor indeed to his giving the sanction of his rank and station, under any circumstances, to the well-directed efforts of a Board, composed of qualified members. But when, on the contrary, we find the Noble Earl, knowing literally nothing of what he is about, engaged in concocting pills and potions, and issuing lengthy directions for locking up the bowels of the entire community, what but ridicule can attach to him? What but the direct interference of those truly qualified—as we have, indeed, had example of in the counter-acting directions issued by the College of Physicians and other genuine authorities—could save the country from the effects of such mischievous interference?

The unfortunate position in which the medical profession is at present placed, by the unsettled state of its general constitution, has, no doubt, tended much to the evil complained of, but we cannot but hope that a better prospect is before us. We are assured by one of our contemporaries, that a settlement of this long agitated question must take place in the course of the ensuing session of Parliament, and the gradual approximation which has been brought about amongst contending parties, gives much reason to hope that he is right. The time, therefore, is come when the great principle should be imperatively laid down—the great fact established—that whatever relates to the conservation of the public health should be placed under the direction of the medical profession. No one, we believe, will be found to deny that the members of that profession, both generally, and as individuals, have established a high claim to the consideration of the public; and it is therefore but the repayment of a long debt of gratitude,—a debt accumulated for ages, that any honours and rewards, suited to their professional calling, which the public may have to bestow, should be

conferred upon them. On this ground alone, independent of the additional claims of the public advantage,—of their peculiar fitness for the duties of all such offices as are connected with the public health,—of the peculiar unfitness of all others for such offices,—it becomes imperative that public medical duties should be alone entrusted to the care of educated medical men.

A Board of Health should be essentially a Medical Board; a Sanitary Commission should be essentially a Medical Commission; for how can the health of the public be entrusted to the care of individuals who know not how to preserve their own, or general sanitary measures to those who are in a great degree necessarily ignorant of the special causes of disease, and of the effects to be apprehended from special morbid agents. The health of the Army and Navy should be placed, as indeed it is, under medical superintendence; military and naval hospitals under the care of medical inspectors; the treatment of the men individually, and the sanitary state generally of the several regimental corps, and crews of vessels of war, under regimental and naval surgeons. So also should the health of that vastly important body, now constituted a civil department of the public service, under the Poor-Law Commission, be entrusted to medical men, and a fitting system of medical attendance, inspection, and control established and committed to those who are alone competent to discharge its duties. A Medical Commissioner is indispensable for this service, and the acting medical officers of Unions should be in medical affairs responsible to him alone, and relieved from all that truckling dependence upon parish and union authorities which disgraces and impedes the operation of the system, as now pursued, and degrades the union surgeon from his professional eminence to a level with a mere clerk or ordinary relieving officer.

These, then, are special points for which the medical press should earnestly contend, and if it is performed with perseverance and energy, and well seconded by the profession generally, (who after all, were they but to act together, would have the settlement of the question in their own hands,) their efforts cannot but be attended with success. The principle laid down is manifestly just and equitable in itself, and it has become a moral duty in the public towards the profession, to

enforce it and carry it out, as well as for their own advantage, that in all their concerns, public or private, the best-qualified officer must be the most efficient, and in the end the most economical.

We beg to call the particular attention of our readers to the notice which appears in this day's Journal, announcing the postponement of the general meeting of the Poor-Law Medical Convention. We learn, with much pleasure, that this postponement will enable Lord Ashley to take the chair, and we anticipate much good to the cause from the presidency of that estimable and benevolent nobleman. We beg, however, to remind Union Medical Officers, that success must depend, in a great measure, on their own exertions, and that they ought to make every effort to support the Committee at the present crisis. We trust that in distant parts of the country delegates will be at once appointed to attend the meeting, and to communicate with the Committee; and we beg to suggest that, of the large number of gentlemen interested in the improvement of Poor-Law management, all those who cannot attend the meeting should, at least, send a subscription.

Review.

Cure of a True Cancer of the Female Breast with Mesmerism. By Dr. ELLIOTSON; with Introductory Remarks by Dr. ENGLEDDUE. London. 8vo. pp. 39. Walton and Co.

In five years over which the treatment of this one case extends, many thousand people have died in England of cancer, and yet a learned physician publishes *this single case as evidence* of the success of a new plan of treatment. And what is more, the only surgical opinion of repute which he quotes, (that of the late Mr. Samuel Cooper,) calls it "a painful tumour, which was believed to be of a cancerous nature," thus throwing doubt as to its cancerous nature at all. The evidence, then, amounts to this:—A woman has a painful tumour of the breast, very like cancer, which, in five years of that very critical period of her life—between 42 and 47 years, is absorbed, her general health having greatly improved, and during this period she was mesmerized, with some intervals. *Valeat quantum valere potest.* If this is to be considered as medical evidence, such as medical men will believe, so as to induce them to recommend or try a new plan, open to the gravest objections, we should feel ashamed of our profession. But that national common sense and judgment which the practice

of medicine (especially in the provinces, where responsibility is not much divided,) fosters, is a guarantee against the propagation of such "mental fevers." That part of the pamphlet which is the most striking for its truth, is the quotation with which it is headed; and as Dr. Elliotson evidently wishes it promulgated, as he has translated it out of Dr. Francis Hawkins' Latin Oration before the College of Physicians, we willingly increase its circulation.

"Do not quacks hunt out the vices or infirmities of mankind to turn them to profit, some selecting one and some another for their purpose? Among quacks, the impostors called *Mesmerists*, are in my opinion, the special favourites of those, both male and female, in whom the *sexual passions burn strongly*, either in secret or notoriously. *Decency forbids me to be more explicit.*

"From these and similar artifices, the physician should be carefully removed and guarded, and this can hardly be accomplished except by a sound education, which will teach him to thoroughly abhor all *deceit and trick*."—*Harveian Oration, delivered by Dr. F. Hawkins, before the London College of Physicians, June 24, 1848.*

The general truth of this we believe. But we would modify the condemnation by stating also our belief, that many impostors impose upon themselves, and thus are not hypocrites, but rather like—

"Katerfelto with his hair on end,
Wondering at his own wonders."

That mesmerism occasionally produces the phenomena of somnambulism, catalepsy, and hysteria, every one who has studied the evidence must believe; but the whole process is so repulsive to men of clear clean minds, and is so open to the vilest abuse, that any benefits which may accrue from it are thought to be too dearly purchased. We thank Dr. F. Hawkins for openly and boldly stating the general opinion. Dr. Elliotson considers it a stigma that the medical profession neglected the facts of insensibility produced by Mesmerism, but at once employed æther and chloroform. Nothing, in our minds, proves more the real soundness of the morals of the medical body. Bodily health is a good thing, but there is something better. It is the pure in heart who see God.

Proceedings of Societies.

BATH AND BRISTOL BRANCH OF THE PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION.

The Quarterly Meeting of this Branch was held at the York House, Bath, on December 21, 1848.

J. C. SWAYNE, Esq., in the Chair.

There were present,—Messrs. Colthurst, Mayor, Morgan, and Ogilvie, from Bristol; Mr. Allen, St. George's; Mr. C. Edwards, Batheaston; Mr. Godfrey, Yatton Keynall; Mr. Jennings, Laycock; Dr. Morgan, Turley; Mr. Vicary, Warminster; Drs. Boyd, Davies,

Goodridge, M'Dermott, Lindoe, Tunstall, and James Watson, Messrs. John Barrett, Brace, Bartrum, George, Hunt, King, Mitchell, Skinner, Stone, and Waldron, of Bath.

SCURVY.

Mr. John Barrett read a paper on scurvy, as it had appeared in the neighbourhood of Bath, in the spring of 1847. (To be published in a future number of the Journal.)

Mr. Hunt observed that the class of cases quoted by Mr. Barrett were found among the poor, but in those in a better station of society he had found that the treatment advocated by Mr. Barrett could not be borne. The cases which had been seen by Mr. Hunt had been chiefly from the age of twelve to twenty years, with bleeding spongy gums, the only common apparent cause being the deficiency in the use of the potato. In treating such cases the first point was to rectify the secretions by purgatives, after which a mixed treatment succeeded best.

Dr. Davies observed that he was sure the meeting must feel obliged to Mr. Barrett for the elaborate paper that had just been read. Mr. Barrett had alluded to the United Hospital, and expressed himself anxious to obtain information concerning the experience of that institution, as regards the treatment of scurvy. As he (Dr. Davies,) was the only member of the medical staff of the hospital present, he would make a few remarks on the subject. Two cases had come under his care as patients of the hospital; one very severe; the other comparatively mild. The first patient had large fungous bleeding vegetations from the gums, almost covering the teeth, and the breath intensely fœtid, the system generally being in a very reduced condition. Both patients recovered rapidly under a generous diet, with porter, and two ounces of fresh lemon juice daily. He objected to the term "land scurvy," as calculated to mislead into the belief that land scurvy and sea scurvy were different diseases, whereas there did not seem any reason for considering them as such, as both are brought about by the same or similar causes,—viz., errors in diet; both present the same symptoms, and are removed by the same means. He thought, moreover, that the reporters on scurvy in different localities had for the most part taken a somewhat narrow view of the cause of the disease. Dr. Christison, for example, had attributed the malady in the Perth Penitentiary to the removal of milk from the dietary; elsewhere the loss of the potato has been considered the exciting cause of the disease. Probably in each case the observer was correct, but the proper induction would seem to be not that scurvy depends on the absence of this or that particular article of diet, but that it depends on some change in the ordinary diet, which involves the loss of that proper mixture of alimentary substances which experience has shown to be necessary for the healthy nutrition of the body.

CHLORINE IN FEBRILE DISEASES.

Mr. Edwards read a paper advocating the use of chlorine in febrile diseases, in solution, as tending to the purification, not only of the excretions, but of the

secretions. This induced a conversation between Mr. Barrett, Mr. Waldron, and Mr. Swayne, the tenor of which was, that though chlorine might appear to remove infection, it only acted as a deodorizing compound, from its absorbing the hydrogen which formed the basis of the various offensive gases; that it must be regarded only as an adjunct to other more efficient treatment, and that, notwithstanding its use, the contagious emanations from the lungs and skins of patients labouring under fever were as potent as without it.

IMPERFECT URETHRA.

Mr. Jennings read the following case of imperfect urethra:—

I was sent for on Dec. 13th, 1848, to see the male infant of Mrs. Fortune, twenty-six hours after birth. I found the penis unusually large, the glans destitute of prepuce, and the urethra absent. I proceeded to lay open the integuments with a bistoury in the mesial line at the junction of the scrotum with the penis; afterwards turning the point downwards, but failing in reaching the blind extremity of the urethra, I passed a sharp-pointed probe slightly curved downwards to the extent of an inch; still no urine flowed. After meditating for a short time whether I should puncture through the perineum, I determined upon making a second attempt with the probe, and on thrusting it about half an inch further, I was delighted upon finding its withdrawal followed by a profuse flow of urine. The case has since progressed favourably without a bad symptom of any kind. I have thought the case interesting, as in the event of a failure in hitting upon the urethra, a question might arise as to the best mode of puncturing the bladder, or whether either would be justifiable in so young an infant, who would most probably pass a miserable existence should the operation be attended with success.

Mr. Colthurst observed that if the operation described by Mr. Jennings failed in infancy, the bladder being almost an abdominal organ, should be tapped above the pubes, you might then probably be enabled, with careful manipulation, to pass a catheter through the vesical orifice of the bladder into the urethra, the extent of which would thus be ascertained in the perineum.

IMPERFORATE ANUS.

Mr. Jennings then read the following case:—

Mrs. Gay was, on the 28th of May, 1848, delivered of a fine male infant. Forty-eight hours after birth, the nurse informed me that she had given the previous day a dose of castor oil, but that having been rejected, together with the food which had been taken, she had repeated the dose, and finding that it had been retained, but without producing any evacuation, she was led to examine the child more closely, and then ascertained the nature of the case. I found the abdominal parietes much distended, and (what I had called the attention of the nurse to at the birth,) the penis tied down to the scrotum by a frænum; indeed there was a raphe running from that point backwards in the mesial line, towards the situation for the anus, at which point there was a slight depression, and I at first imagined that it

would only be necessary to puncture with a bleeding lancet. But this failing to reach the bowel, I plunged a trocar and canula upwards and backwards to the depth of an inch and a-half, through what I imagined to be fat and cellular tissue, but on withdrawing the trocar, no meconium escaped. I then made a second moderate thrust of about half an inch, when, on again withdrawing the trocar, I was gratified by an abundant flow of meconium. I afterwards enlarged the canal with a bistoury, with the loss of but a few drops of blood, and directed the nurse to pass a candle occasionally up the part (having no bougie then with me,) to prevent union by the first intention. The child continued to go on well up to the end of a month, when he evidently lost flesh. Castor oil and rhubarb, with magnesia, &c., were occasionally administered, but still he did not thrive, and at the end of two months died. I observed that the abdomen was generally unnaturally distended, although the calibre of the artificial anus was amply sufficient for the passage of the fæces, which were natural in every respect.

I regret that a *post-mortem* examination was not allowed, as I had no means of otherwise judging to what extent the canal had been shortened by the process of absorption, or whether a sphincter existed, although of that I have little doubt, as the aperture was generally closed when I examined the child.

[Since the narration of this case at our quarterly meeting at Bath, I have met with one almost precisely similar, recorded by Mr. Hutchison, in the *Medical Gazette* of Feb. 2nd, 1828, in which death, after five weeks, is attributed to the neglect of the nurse, and I am much inclined to impute it in this case to a similar cause.]

Mr. Swayne had seen several cases of imperforate anus and rectum. In one case the anus was not imperforate, in the others it was. In the former case about half an inch above the anus a swelling could be felt; this was pierced, a bougie was passed up, and the child recovered the use of the bowels. She lived for seven years afterwards, and experienced no inconvenience. In two other cases he had attempted to make a passage, but had failed. On examination it was found that there had been no tendency towards the anus; the rectum ceased abruptly, was adherent to the left side, and had not entered the pelvis at all.

Mr. Jennings then narrated two cases of laceration of the perineum.

BIRMINGHAM PATHOLOGICAL SOCIETY.

July 6th, 1848.

V. W. BLAKE, Esq., in the Chair.

DISEASED HEART: HYPERTROPHY, WITH DILATATION OF LEFT SIDE; DILATATION OF RIGHT SIDE.

Robert Davis, aged 64; countenance thin and anxious; features cramped. He is much emaciated, and suffering extreme debility. Skin cool; extremities cold; tongue furred and moist; thirst; pulse 70, irregular, and thready; bowels regular; urine reported deficient in quantity, and high coloured; breathing very laboured, cough, and slight expectoration; dyspnoea increased on

anything being taken. On taking fluids a portion returns through the nostrils, accompanied with aggravated dyspnoea. There is occasional spasmodic difficulty of breathing. He is a brass-founder by trade; has followed a steady regular course of life since a young man. His illness first made its appearance soon after Christmas last, commencing with influenza. Has been under treatment at different times; has been subject to neither fever nor dropsy. Ordered, R. Vini. Ipecac., dr. iij.; Tinct. Opii, dr. j.; Sp. Ætheris. Sulph., oz., ss.; Aq. Camph, oz. vii. M. Fiat Mist.; sum., oz. j., quartis horis. Two glasses of wine daily; beef tea, arrowroot, and meat daily.

June 27th. Passed a very restless night. Urine, of specific gravity, 1024, acid, contains no albumen. 28th. Continues much the same. 29th. Tongue dry and brown; complains of great thirst; is exceedingly weak; breathing more laboured; pulse irregular and thready. 30th. Died at half-past six o'clock, a.m.

Dissection.—Body emaciated. Brain and membranes healthy. Thorax:—Right pleura adherent at apex; left slightly so. Structure of right lung softened, greatly emphysematous, and distended with abundant dark frothy serum; left lung far more healthy, diseased after the same manner in parts; no tubercles. Heart weighed twenty-four ounces; pericardium contained no larger a quantity of serum than natural; was adherent for about an inch to the anterior aspect of the left ventricle. The left cavity showed the walls of the ventricle thickened, and the cavity increased. The mitral valves, with the cords, were greatly enlarged, edges irregular, and the cords twice their natural thickness; left auricle partaking of the general enlargement, otherwise natural. Walls of right ventricle atrophied; capacity increased; tricuspid, aortic and pulmonary valves healthy; sinus aorticus showed abundant atheromatous deposit. The right auricle, on its external aspect, presented its appendix greatly enlarged, dark, and to the fingers, evidently containing a firm material; the interior showed the cavity far larger than in proportion to the other parts of the organ, and the appendix filled up by a considerable deposit of dark-coloured fibrin, regularly deposited in layers, one over the other, as in an aneurism, and this evidently did not form a recent deposit. The coronary arteries were pervious to a large sized probe. Liver contracted in size. Kidneys small; structure friable; proper tunic preternaturally adherent; fatty under the microscope. Pancreas healthy; spleen soft and friable.

Dr. Fletcher said that this was a case of dilatation of the right side of the heart, and stagnation of blood, and consequent coagulation in the sacculated dilated appendix of the auricle, from impeded circulation through the lungs, in consequence of old disease.

Mr. Swain presented a diseased tibia, occurring in a boy, aged 16, for which amputation above the knee was performed. A portion of the bone was necrosed and loose, but was not quite separated.

MALIGNANT DISEASE OF THE LOWER JAW.

Mr. Alfred Baker gave the history and treatment of the following case:—

William Tomkins, aged 17, a tall, spare, and delicate-looking young man, was admitted into the Birmingham

General Hospital, on June 23rd last. He states that six months back he noticed a "little hard lump as big as a horse bean," about the centre of the right horizontal ramus of the lower jaw. It could not be moved or pinched up with the cheek, seemed to be firmly connected with the bone, and was quite free from pain. In about six weeks it had attained the size of a walnut, and became the seat of dull aching pain, which was constant, with lancinating pains which were only occasional. He now applied for surgical advice and had the swelling leeches and blistered. These measures seemed to arrest the growth for three weeks, when it again enlarged and began to project within the mouth so as to interfere with mastication. The pain at the same time became aggravated. Some iodine application was now made to the tumour. Shortly afterwards two of his molar teeth were found to be loose, and were extracted, and their removal was followed by considerable bleeding. The sockets from whence they were extracted were soon filled up by the diseased mass, which enlarged in a forward direction so as to displace the two teeth in front of those already removed. These last were taken out six weeks back, immediately after which the inner or oral portion of the swelling enlarged and advanced towards the commissure of the lips, whilst the outer or maxillary portion extended downwards to the neck, so as to form a tumour projecting from the jaw-bone as large as an orange, "and as hard as a stone." Since then, its extension has been most rapid in every direction. It has encroached upon the mouth so as to prevent him taking any solid food, and outwardly has enlarged so as to equal half a cocoa-nut in size. The pain has become severe, and in addition to a constant dull aching and sense of tension, he has violent lancinating paroxysms. Within the last few weeks the consistence of the mass has changed and become softer. The tumour has a broad base extending from the last right inferior molar tooth to the left canine tooth, and from the level of the teeth in the upper jaw, downwards over the neck so as to cover the right superior lateral cervical triangle. The basal portion is firm, elastic, and covered by healthy skin, whilst the apex which points downwards has a soft pulpy, and semifluid feel, and is covered by inflamed integument, and is of higher temperature than the surrounding parts. The mouth is kept open by the projection of the mass within, which reaches from the right last molar tooth forwards beyond the commissure of the lips, imbedding the right canine and incisor teeth; it fills up the space between the cheek and jaw, and occupies the right half of the cavity of the mouth, pushing the tongue to the left side. Its upper surface is deeply channelled by the pressure of the upper teeth. It is of an ashy-grey colour, of moderately firm consistence, and is the seat of several ulcerations from bruising by the teeth, and the attrition of such soft food as he can take.

July 5th, I this morning removed the growth, and the portion of the lower jaw to which it was connected, by an elliptical incision, extending from the angle of the mouth over the swelling to near the lobe of the ear, the ellipsis including the livid skin covering the apex of the tumour. Another incision was required, extending from the lower line of the ellipse at right angles to the left side of the

chin. The upper flaps were first reflected, the cavity of the mouth opened, and the bone sawn through behind, close to the last right molar, and in front, through the alveolus of the left canine. The mass thus loosened was now seized and drawn upwards, whilst the lower flap was dissected off, and the tumour, with the portion of jaw from whence it sprang, detached. From six to eight ounces of blood were lost during the operation. Five ligatures were applied, and the parts were brought together by sutures and strips of adhesive plaster.

The growth sprang from the cancellated tissue of the bone, into which it could be traced, having separated a fragment of the dense outer tissue of the jaw. The portion projecting over the neck was enclosed in a cellular capsule, which could not be traced over the part projecting into the mouth. Its section displayed two kinds of formation, the upper or oval part being indistinctly lobular, of yellowish white colour, and firm texture, whilst the lower or cervical part was one large lobe of pure white colour, lardaceous appearance, and so friable as to crush under slight pressure. The uniformity of its colour was only here and there broken by a few cells, containing blood, and a few patches and streaks, apparently resulting from ecchymosis.

SHEFFIELD MEDICAL SOCIETY.

Third Meeting, November 22nd, 1848.—The President, Dr. Bartolomé, in the Chair.

HYPERTROPHY OF THE LEFT VENTRICLE OF THE HEART; DISEASED AORTIC VALVES.

The President exhibited the heart of a man, aged 30, who was admitted into the Infirmary September 1st, 1848, when he presented symptoms of eccentric hypertrophy of the left ventricle and obstructive disease of the aortic valves, but, although carefully examined on four separate occasions, no other abnormal sound could be detected. The last examination was made seventeen days before death.

The *post-mortem* examination took place thirty hours after death. The heart weighed fourteen ounces and a half; the left ventricle was considerably hypertrophied and dilated; the aortic valves were opaque, thickened, and wrinkled, more particularly so at their edges, so as not quite to close the aortic orifice; on one of the segments of the valve was a slender vegetation, about one-eighth of an inch in length; the membrane lining the aorta presented considerable atheromatous deposit, but the extent to which this existed was not ascertained.

PENDULOUS TUMOUR OF THE LABIUM PUDENDI.

Mr. H. Jackson then detailed the particulars of a case of pendulous tumour of the labium pudendi, which by the kindness of Mr. Law he had lately seen, and removed. The records of such cases are comparatively rare, and he was on that account induced to place it upon the minutes of the Society.

Elizabeth B., aged 44 or 45, the wife of a pocket-knife cutler, (who for nine years has been an inmate in a

lunatic asylum,) has had six children, four of whom are now living. The eldest, now dead, was born twenty-four years ago. The youngest, still living, is now nine years of age. Her oldest living child is nineteen. Her husband, when able to work, earned good wages, but having been incapacitated for thirteen years, four years before he was placed in the asylum, she has supported herself and family on a very scanty income, derived partly from the parish funds, and partly from her own exertions as a washerwoman. The catamenia have always been profuse, but during the last five years she has, she thinks, been one-half her time unwell, the discharge generally continuing for about ten days, with an interval of cessation of a like duration. Otherwise her health has been very good.

In October, 1846, she first perceived a small tumour growing from the left labium, which steadily increased, and in the course of twelve months from being first discovered, had, she thinks, reached half its present bulk. About this time the lower and most depending surface became ulcerated, and a scanty discharge, of a sero-sanguineous character took place. She is unconscious of having felt sensation of any kind in the tumour until about four months ago, when she experienced pain, apparently resulting from the mere weight of the tumour, extending from it to the left groin, and downwards to the left thigh. It gradually increased, and became so much a matter of annoyance, that she could not follow her occupation of washerwoman, and she at length overcame her scruples, and mentioned it to Mr. Law, who advised her to come into the Infirmary, but she refused to do this, and he then kindly requested Mr. Jackson's assistance.

On examination a large tumour was found hanging down between the legs, suspended by a peduncle of at least two inches in length, to the upper and front part of the left labium. The lower surface was ulcerated. The tumour was irregular in shape, being in some places hard, and giving the sensation of being very irregular in structure. On seizing the peduncle between the finger and thumb, two arteries of considerable size were pulsating very evidently.

The question as to knife or ligature, as allowed by authors in these cases, seemed to be settled at once by the size of these two arteries, it being thought advisable to use the former when they would be more certainly secured by ligatures, and the frequent recurrence of menorrhagia, made it desirable not to incur the risk of losing any blood by secondary hæmorrhage. The patient acknowledged that she had frequently entertained the idea of cutting it off herself, but the fear of hæmorrhage had fortunately restrained her. The peduncle was removed by a single stroke of the scalpel. The two arteries were secured by ligatures; the edges of the wound were drawn together by two sutures, and covered by elastic-gum sticking plaster. The healing process was soon completed, but she has suffered from the usual menorrhagic symptoms, and is yet in a weak state from that cause, and the want of a sufficient nutritious support. The weight of the tumour was nine ounces and three quarters, and was of the usual fatty structure, here and there condensed. It was clearly not malignant, and contained no fluid.

The reader of the case exhibited three drawings of a

tumour taken from the upper portion of the labium of a female who came under his care in the Infirmary some years ago, presenting the appearance of hydrocele, being equally pear-shaped and smooth, and containing a considerable quantity of fluid, as shown by its transparency; but the patient would not submit to the slightest operation, and merely required a suspensory bandage, which she obtained, and the result was never known.

Mr. Ray stated that he had once had a tumour of a similar character to the specimen on the table under his care.

Foreign Department.

CLINICAL MEDICINE AND SURGERY IN THE CONTINENTAL HOSPITALS.

Nocturnal Incontinence of Urine: Blisters.—A young girl, aged 13, in good health, was admitted into the Hotel Dieu under M. Guerard, the subject of incontinence of urine from the age of four years. She wetted her bed every night during her dreams. M. Guerard applied a blister over the pubic region, the action of which effected a temporary cessation of her disgusting infirmity. The blisters were repeated with the same results, but it does not appear that a cure was effected.

Acute Rheumatism treated by Nitrate of Potash.—A man aged 30, convalescent from syphilis, was seized with fever and swelling of both knees with copious effusion of synovia. The patient had never previously been the subject of rheumatism, and it was at first doubtful whether the case was one of common or gonorrhæal origin. Next day, the joints of the upper extremities became affected, the knees were enormously enlarged, and the pulse got up to 100. M. Martin Solon prescribed six drachms of nitrate of potash in lemonade, to be taken during the day. The next day the amendment was considerable, the pulse fell to 80, and the swelling of the knee had diminished; the treatment was continued, and in two days more the joints were nearly of the natural size, and convalescence was established. Cases of this kind are said to be of daily occurrence in the wards of M. Martin Solon, who invariably treats acute rheumatism in this manner. The dose is sometimes carried to the extent of two ounces per diem. If there be accompanying endocarditis he takes blood from the arm. It is to be remembered that this salt is an energetic poison, and the health has been destroyed by one ounce; but the French physicians consider that in inflammatory disease a tolerance is established, which renders a dose of medicine salutary, which in health would be injurious.

Treatment of Severe Uterine Hæmorrhage by the Actual Caustery.—For many years M. Jobert has been in the habit of treating severe uterine hæmorrhage (in the unimpregnated state we presume,) by the actual cautery to the cervix. There are at this time in his wards six women, who were exsanguine and as it were dying, when the hæmorrhage was arrested by a single

cauterization, and they have now regained their flesh and colour. Of these, some were the subjects of ulcerated carcinoma; others laboured under hypertrophy of the cervix, with granular ulceration. A third variety treated by M. Jobert in his private practice, comprises those known as purpuric hæmorrhages.

The cautery which he uses is of a globular form, and is applied with the aid of a large ivory speculum, over the whole bleeding surface, and is held in contact sufficiently long to cause a deep eschar. The patient experiences no pain and the vagina is immediately washed out with cold water. From this time the hæmorrhage generally ceases for some days, but as the eschar becomes detached, leucorrhœa, and finally, hæmorrhage reappears. The cautery is then applied a second time, and produces the same effect. By this the hæmorrhagic tendency is further checked, and the fœtidity of the discharges much lessened. A third and future cauterization if necessary, becomes so at longer intervals. In the meantime the patient recovers her strength, and may take iron and quinine. The cancer is by the above means checked, but not cured, and if left to itself, the same symptoms would reappear, but it has been observed in many cases, that if the patients are occasionally examined, and fungous granulations checked by the cautery, life may be indefinitely prolonged. When the hæmorrhage depends upon simple hypertrophy with ulceration, a perfect cure is effected in two or three months. Passive hæmorrhages are treated by M. Jobert, by cauterizing the os and cervix, even though there be no ulceration.

ABSTRACT OF THE PROCEEDINGS OF THE ACADEMIE DES SCIENCES, PARIS.

PLUGGING THE VAGINA IN UTERINE HÆMORRHAGE.

M. Velpeau read a report on the memoirs of MM. Miguel and Du Hein, on a particular mode of plugging the vagina in the hæmorrhages of pregnancy. The method consists in inserting a pig's or sheep's bladder furnished with a stop-cock, into the vagina, and inflating it with air or filling it with cold water. M. Miguel recommends that it should even be inserted into the womb itself in post partum hæmorrhage.

EFFECTS OF QUININE IN LARGE DOSES.

M. Briquet, presented a memoir entitled "Experimental Researches on the Properties of Quinine in Large Doses, and its Therapeutical Uses." By large doses, the author means from fifteen to thirty grains.

In his researches, the author studies in succession the effects of large doses of quinine on the principal organs of the economy, as for instance on the organs of circulation, on the nervous centres, organs of respiration, digestion, generation, &c.

According to M. Briquet, the organs of circulation present two especial modifications; the first which affects the number of pulsations of the heart, shews that these may be diminished from eight to forty beats in the course of a few days. The force of the pulse he

has studied with the aid of the hæmadynamometer of M. Poiseuille, applied to the carotid at the same time that quinine is injected into the jugular veins. He has thus ascertained that the force may be diminished in all degrees from one-tenth to complete annihilation, according to the dose injected, and that thirty grains is sufficient to cause immediate death. He has therefore concluded that quinine exercises a directly debilitating effect on the heart's action.

The brain and its dependencies exhibited different phenomena according as the quinine reached the brain directly or indirectly. When injected into the carotid arteries, it produced excitement, and in some cases convulsions followed by prostration, but if injected into the aorta, there was less excitement, and a more rapidly sedative effect.

The respiratory organs were not sensibly influenced; the digestive organs were slightly injected when a moderate dose had been given, and were vividly inflamed when large doses had been given several days in succession.

M. Briquet has never known abortion produced by quinine, as has been maintained by some.

From the study of the physiological action of quinine, the author deduces his views of its therapeutical value. Thus he supposes that from its power of reducing the pulse, it may be useful in the pyrexia in rheumatism, gout, erysipelas, and other diseases accompanied by high action. The action on the brain may be taken advantage of, in cerebral neurosis, periodic neuralgia, &c.

Children and young people are readily influenced by quinine, and its absorption is rapid, but they can bear larger doses than adults. Bleeding augments the susceptibility to the effects of quinine in a notable manner. After some further remarks on the action of opium and coffee, when given in conjunction with quinine, the author draws the general conclusions:—

1. That quinine depresses nervous power, especially that of organic life.

2. That it is a direct excitant of the organs with which it comes into contact, in this respect resembling æther and chloroform.

ABSTRACT OF THE PROCEEDINGS OF THE ACADEMIE DE MEDECINE, PARIS.

ON CHLOROFORM INHALATION.

The sittings of this academy during the month have been mainly occupied with a discussion on a report by M. Malgaigne, on the fatal cases from chloroform inhalation. The author narrates each case which has occurred with minuteness and accuracy, and as the result of his enquiries determines, that it is an agent of great power; that it should not be exhibited in persons labouring under diseases of the lungs or heart, but that in healthy persons it is perfectly harmless when administered with due regard to proper dilution with atmospheric air, and to its withdrawal as soon as the signs of insensibility are apparent.

General Retrospect.

SURGERY.

IMPACTION OF A HALFPENNY IN THE PHARYNX FOR EIGHT MONTHS.

A boy, aged one year and eight months, came under Dr. Ward's care, June 23rd, when his breathing was so loud and stridulous that it resounded through the hall in which he was waiting. As soon as Dr. Ward saw him, the child began to cry so convulsively, and was seized with such violent coughing, that a close examination of his throat was impossible. He was pale and emaciated, and seemed decidedly phthisical. The glands of the neck were somewhat enlarged, and the chest sounded well on percussion. His mother observed that he was quite well and hearty till March 3rd, when she supposed he swallowed a halfpenny with which he was playing, as he began to choke immediately, and the coin could not be found afterwards, and from that moment his breath became stridulous. She was then in Coventry barracks, and she took him to the regimental surgeon, who, thinking it an attack of irritation from teething, merely gave him some castor oil. At this time, besides the dyspnoea, he was constantly dribbling a thick mucus, and he could only suck one mouthful of milk at a time, being forced to withdraw from the breast with each effort of swallowing. The mucus was so profuse as almost to choke him; and these symptoms, with an increasing cough, continued for three months, till a short time before he came under Dr. Ward's care, when the dribbling had almost ceased. The mother next took him to the Coventry Hospital, where the case was again considered to be laryngismus from teething, and was treated accordingly. Dr. Ward concluded that the bronchial glands were affected with tuberculosis, as well as those of the neck, and, pressing on the recurrent, were causing the stridulous breathing. He therefore prescribed an iodine liniment, and the syrup of iodide of iron. Under this treatment the child rapidly improved, with occasional relapses, and thus seemed to confirm his diagnosis, when, on October 25th, his mother brought him, looking comparatively well, and produced the halfpenny, which she said he had taken out of his mouth and put into his father's hand, after a severe fit of coughing, the day before. There is now, however, considerable hoarseness when he cries or coughs, the latter symptom not having ceased with the removal of the cause. The coin was much worn and corroded, and covered with a layer of dried mucus.—*London Pathological Society in Medical Gazette.*

MEANS OF RECOGNIZING THE SENSIBILITY OF THE RETINA IN CERTAIN CASES.

M. Cuhier, when he wishes to ascertain whether the retina retains its sensibility, compresses the eye-ball at one of its angles; if the luminous ring appears at the opposite corner, he decides that the sensibility of the retina is perfect, if it does not appear, the contrary is presumed. M. Cuhier has never observed this effect of lateral pressure in amaurosis, but it is present in cataract

and other defects of vision depending upon diseases of the transparent media of the eye.—*Annales d'Oculiste*, Avril, 1848.

OBSTETRIC MEDICINE.

PROLAPSE OF THE GRAVID UTERUS DURING LABOUR.

By E. T. Watson, M.D.

On Thursday, the 13th of January last, about eight o'clock in the morning, Dr. Watson was called in haste to visit Mrs. C., aged about 22 years, in labour with her first child. On arriving at the house he found her in charge of two midwives, who had been with her the greater part of the preceding night. The patient was lying on the floor, with a few bedclothes under and over her. Being requested to examine the case and do something immediately for the relief of the patient, as the midwives and friends were very much alarmed at her condition, he found the uterus entirely without the vulva, containing a fœtus at full term of uterogestation. When placing his hand on the uterus, he found it dry and ecchymosed in several places on the body and fundus, with the os uteri dilated to about the size of a twenty-five cent piece, and very thick, firm and unyielding, with the scalp slightly projecting through the orifice. Upon enquiry, he learned that early in the night the patient had been taken in labour, and the midwife first called to the case finding something unusual exhibiting itself, desired a physician to be sent for; the friends objecting, they sent for the second midwife, who thought herself able when she arrived to surmount every difficulty, and bring the labour to a speedy and successful termination. But after exhausting all her skill, and making the case no doubt a great deal worse by her efforts for delivery, she then advised the friends to send for a physician with all possible speed. Dr. Watson had the patient taken up and placed in bed as soon as possible, and applied linen clothes, rung out of warm water, to the uterus, and sent for Dr. J. S. Bracken to come to his assistance and bring the necessary instruments for delivery, having none with him but a common case of midwifery instruments and a small scalpel or two. After several applications of the linen (which were renewed every five minutes,) he found the uterus began to act, and with such force as to give strong fears that a laceration of the organ might take place. The pains, though frequent and very strong, had no effect in enlarging the os uteri. Deeming the case too urgent to wait any longer for the arrival of Dr. Bracken, he determined to divide the neck of the uterus longitudinally, and for that purpose introduced his finger in the absence of pain, and with a common scalpel, the finger serving as a director and also protecting the scalp of the child, divided the neck to the extent of three-quarters of an inch or more. Another pain soon came on, which caused but little dilatation. Owing to the cartilaginous condition of the cervix, he thought it best to make two other incisions, about equidistant from the first, and to about the same extent; after which, the pains having returned, the fœtus was expelled in a state of asphyxia, but by repeated inflation of the lungs and using the common restoratives, it was soon discovered to breathe, and in

a short time cried out lustily, to the gratification of mother and friends. The placenta was soon delivered without difficulty or hæmorrhage, the uterus contracting firmly, as though it had been in its proper position. By this time Dr. Bracken having arrived, and having examined the case—the parts being cleansed—Dr. Watson then returned the uterus to its proper position, applied a large piece of sponge, well oiled, to the vagina, and secured the same by the application of a T bandage. The woman perfectly recovered.—*Philadelphia Examiner*, April, 1848.

TOXICOLOGY.

POISONING BY ARSENIC: SYMPTOMS DELAYED.

[The following case, which is of the utmost importance in a medico-legal point of view, is reported by Mr. Clegg, of Boston.]

On Sunday, August 27th, at four o'clock in the afternoon, a woman requested me to visit her niece, who had taken poison. Her own suspicions had been aroused a few minutes before, by finding a white powder at the bottom of a cup when she was preparing the tray for tea. She accused her niece of attempting suicide, and the girl sullenly admitted having taken a teaspoonful of "white mercury" before dinner—that is before half-past twelve o'clock.

I accompanied the woman, and found a heavy stupid-looking girl, aged 17 years, sitting in a chair, more asleep than awake. On being roused she reeled about the room as if intoxicated; indeed, I at first suspected poisoning by a narcotic. But a paper parcel was brought to me evidently containing arsenious acid, and from this parcel the girl declared she had abstracted and swallowed the poisonous dose. She appeared to be in no distress; she had no acrid eructations; no burning pain in the throat or at the epigastrium; no vomiting; no diarrhœa. She had been once sick after dinner, but now the stomach was not irritable. All she desired was to be allowed to go to sleep; and narcotism appeared to be the only present symptom (if symptom it may be considered,) of poisoning by arsenic.

The sulphate of zinc soon produced free vomiting, which was maintained for half an hour, mucilaginous drinks being also administered. At the expiration of this time, Mr. Small, another medical man, arrived with a jar of the hydrated peroxide of iron; and, having a very pressing engagement, I left the patient with my friend, who administered large doses of the antidote. At nine o'clock the same evening we visited her both together. She was in bed, making no complaint, and disposed to sleep quietly. The belly was not tender; diarrhœa was still absent, and all vomiting had ceased.

At ten o'clock the following morning the aunt called upon Mr. Small to inform him that her niece was quite well: "Might she go a gleanng." Up to half-past eleven o'clock the girl continued more than ordinarily cheerful, and was busied in preparing the family dinner. At half-past eleven o'clock she suddenly complained of an excruciating pain in the body, with excessive prostration of strength. She went to her bed-room to lie down, and at twelve o'clock was discovered dead, having fallen by the bed-side. How many minutes she lived

after the first expression of pain, and the nature of the symptoms immediately preceding dissolution, I am unable to relate; but, as she was never heard to move or to speak after going up stairs, I am of opinion that she was just able to crawl to the side of her bed, and died instantly. Thus the fatal result occurred in about twenty-four hours after taking the poison, and within half an hour after the first decided symptom of poisoning was manifested.

Sectio cadaveris, forty-eight hours after death. The mucous coat of the stomach was much corrugated; the stomach itself appeared small and contracted, and numerous reddish-brown patches were diffused over the inner surface; the peritoneal coat was not affected. Slight traces of inflammation were apparent in the duodenum and intestines. Six ounces of a thin, shreddy, brownish-coloured fluid were removed from the stomach for the purpose of analysis; and I may add, briefly, that the vomited matter, the fluid removed from the stomach after death, and the fluid in which the stomach and first part of the intestines were boiled, most carefully tested by Mr. Small and myself, yielded abundant evidences of the presence of arsenic.

Observations.—This case is one of exceeding interest in a medico-legal point of view. In ordinary cases the symptoms of poisoning by arsenic are manifested within half an hour; very rarely have they been delayed for one hour. Two, three, and four hours have, however, been known to elapse. Orfila relates a case in which symptoms were delayed for five hours, and then but feebly developed; the patient died, nevertheless, within nine hours; and this case he considered the most extraordinary on record. The trial of Mary Smith, at Edinburgh, in February, 1827, may also be cited. Poisoning by arsenic was undoubted, "but," says Christison, "the symptoms did not begin till more than eight hours after the only occasion on which the prisoner was proved to have administered anything in a suspicious manner:" upon this evidence she was acquitted. In the late editions of his "Treatise on Poisons," Dr. Christison observes, in reference to this case, "The intervening state of sleep probably affords an explanation of the long interval, and I am not sure that I should now feel the same difficulty."

These circumstances considered, I have thought it highly important to place upon record the case above related, as it demonstrates clearly that arsenic, in a dose sufficient to produce death, may remain in the stomach for a period of *twenty-three hours* without producing the well-known decided symptoms. One observation more I think it requisite to make. The lower classes in Lincolnshire are much addicted to the abuse of opium, and I have reason to believe that this girl was a laudanum-drinker. It has since occurred to me that her case might be an example of compound poisoning. Is it possible that the action of one poison could so far mask the evidences of the other? Did the opiate suppress the intolerable agony which ordinarily attends the administration of arsenic, whilst it possessed not the power to interrupt or prevent the deadly result?—*Medical Times*, Oct., 1848.

PROCESS FOR THE MORE CERTAIN DETECTION
OF ARSENIC.

Dr. Geoghegan proposes the following procedure by which a given quantity of arsenic may be transferred undiminished to each of the fluid tests in succession. As minute precautions in manipulation vitally affect the result, he premises that want of success in the application of the fluid-tests to small sublimate, sometimes arises from not reducing the latter to powder before attempting their solution. The sublimate being carefully detached by a glass rod, aided by a fine stream of distilled water, should be received in a small porcelain mortar, and carefully triturated. The solution having been effected by boiling, should (1) be precipitated when cool, by ammonio-nitrate of silver. The yellow arsenite obtained is to be next decomposed by a slight excess of pure hydrochloric acid, and the filtered solution treated (2) by a current of sulphuretted hydrogen. Having ascertained the solubility of the resulting sulphuret in ammonia, it should now be dissolved in nitro-muriatic acid, and evaporated to dryness, (avoiding excess of heat at the close,) re-dissolved and precipitated (3) by nitrate (or ammonio-nitrate) of silver, which yields the brick-red arseniate (4.) Finally, the latter being decomposed by hydrochloric acid, in minimum quantity, the filtrate should be heated with a few drops of an aqueous solution of sulphurous acid, the excess of the latter expelled, and hydrated oxide of copper, with ammonia, in minute quantity, added. We can thus elicit the reactions of the *four* fluid tests from a quantity of arsenious acid which would prove refractory by the common method of subdivision, and are hence enabled to ensure a satisfactory issue in difficult cases. The final step of the operation is not always successful, the ammonio-sulphate of copper being, even in experiments on larger quantities, a much less delicate test than those previously named. Having obtained, however, the antecedent results, the evidence of the presence of arsenic may be deemed complete. Modifications of the foregoing method will at once suggest themselves, and may be adopted at pleasure. It may occur to the instructed reader, that the success of the copper test might be secured by re-precipitation and sublimation of the arsenic subsequent to the formation of arsenite of silver; as, however, there is reason to believe that no inconsiderable portion of the metal is often retained by the copper foil as an arseniuret, this procedure is not to be recommended.—*Medical Gazette*, October 6th, 1848.

ACUTE LARYNGITIS.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND
SURGICAL JOURNAL.

SIR,

I cannot resist writing to corroborate the truth of Mr. Norman's observations on the case of acute laryngitis, inserted in your last number. A precisely similar case occurred in my practice last summer, with the exception that the sufferer was a woman. It is not necessary to go into details, for the above reason, the

patient being also treated on the same plan, except the venesection, which did not appear admissible from the depression observant at the time. I confess to you, prior to the fatal termination of the case, notwithstanding the absence of urgent symptoms justifying such a measure, I had nearly proposed the operation. Now, that such an authority as Mr. Norman has suggested it, should I meet with another case of a like nature, I should, were it permitted, unhesitatingly resort to tracheotomy. Happily, laryngitis is a very rare affection, but being also so fatal, I have felt justified in taking the liberty of drawing the attention of the profession, through your widely spread Journal, to the necessity of adopting Mr. Norman's suggestion in this intractable disease, and thereby, perhaps, removing another stigma from the value and usefulness of our noble profession.

I am, Sir,

Your obedient servant,

W. A. RACKHAM, M.R.C.S.E., &c.

Wangford, Suffolk, January 16, 1849.

NOTICE OF THE LATE DR. JAMES COWLES
PRICHARD, F.R.S.

Dr. Prichard, who was born at Ross, in Herefordshire, settled as a physician in Bristol, in the year 1810, and was a few years after appointed physician to the Clifton Dispensary and St. Peter's Hospital. In addition to his professional avocations, he occupied himself, at this period, in writing the first edition of his "Researches into the Physical History of Man," which appeared in 1813, and his work upon "Egyptian Mythology." In the year 1816, he was elected Physician to the Bristol Infirmary, which appointment he filled in conjunction with that of Physician to St. Peter's Hospital; and in the year 1822, he published a work on the "Diseases of the Nervous System." In 1829, he wrote a small octavo work, entitled "An Essay on the Vital Principle," dedicated to the patrons of the Bristol Philosophical Institution, of which he was one of the founders, and where he frequently gave lectures, and read papers on various subjects. He also took an active part in founding the Bristol College, and was, for many years, one of the members of its council. The degree of Doctor of Medicine of the University of Oxford was conferred upon him, by diploma, upon the occasion of his reading the Anniversary Address at the meeting of the Provincial Medical and Surgical Association, held in that city, in the year 1835. Dr. Prichard was one of the Visiting Physicians of the Gloucestershire Lunatic Asylum, and a Metropolitan Commissioner in Lunacy before his appointment under the recent Act. About this time he wrote his work on "Insanity," a book upon the "Eastern Origin of the Celtic Language," and a little volume on insanity, as connected with jurisprudence, and contributed various articles to the "Cyclopædia of Practical Medicine," and the "Library of Medicine." In the year 1845, he was appointed one of her Majesty's Commissioners in Lunacy, and removed to London, where, besides the active duties of

the commission, he completed the third edition of his "Physical History of Man," in five volumes, as well as his popular work on the "Natural History of Man." He was a Fellow of the Royal and a great number of British and Foreign Societies, and at the time of his death was President of the Ethnological Society of London. In his intercourse with his professional brethren and colleagues, Dr. Prichard's conduct was straightforward, honourable, and generous; to his patients he was gentle, attentive, and kind. High moral and religious principle, an affectionate disposition, an instinctive sentiment of delicacy, propriety, and consideration for the feelings of others, together with a retiring modesty and simplicity of deportment, as much distinguished and endeared him in the domestic and social relations of life as his literary and scientific attainments have elevated him to the eminence he held in public estimation. He furnished, indeed, a bright example of the scholar, the gentleman, and the Christian.

Medical Intelligence.

APPOINTMENTS.

J. F. South, Esq., the Translator of *Chelius' Surgery*, and one of the Surgeons of St. Thomas' Hospital, was elected a Member of the Court of Examiners of the Royal College of Surgeons, at the meeting of the Council, on the 11th instant, in the vacancy occasioned by the lamented decease of Mr. Samuel Cooper.

William Fergusson, Esq., Professor of Surgery in King's College, has been elected Consulting Surgeon to the Hospital for Consumption, in the room of Mr. Liston, deceased.

John Bleack, Esq., has been appointed Surgeon to the Bristol Gaol, in the room of George Hetling, Esq., resigned.

Samuel Gaskell, Esq., F.R.C.S., and lately the Superintendent of the Lancaster County Lunatic Asylum, has been appointed by the Lord Chancellor, a Commissioner in Lunacy, in the room of Dr. Prichard, deceased.

HUNTERIAN ORATION.

The Hunterian Oration for 1849 will be delivered on the 14th of February, by Cæsar Hawkins, Esq., Surgeon to St. George's Hospital.

ACADEMIE DES SCIENCES, PARIS.

M. Boussingault has succeeded as President of the Academy, for the year 1849. M. Duperrey has been elected Vice-President, in the room of M. Boussingault.

Sir D. Brewster has been elected a Foreign Associate, in the room of M. Berzelius, deceased, by a considerable majority, Messrs. Tiedemann, Mitscherlich, Ehrenberg, and Melloni, having been also put in nomination.

ROYAL COLLEGE OF SURGEONS.

Gentlemen admitted Members, Friday, January 12th:—W. S. Love; J. Bull; W. Bell; J. A. Bolton; W. E. Jefferys; W. Briscoe; A. G. H. Buckby; T. Wade.

SOCIETY OF APOTHECARIES.

Gentlemen admitted Licentiates, Thursday, January 11th:—James Mitchell, Nottingham; Henry Edward Turnour; Charles Newth Foote, Sheffield; George Tootal Nicholson, Sheffield.

OBITUARY.

Died, December 30th, at Altrincham, Cheshire, aged 66, Samuel Hibbert Ware, M.D., F.R.S.E., &c.

January 6th, aged 79, Charles Edward Clarke, Esq., formerly Assistant-Surgeon in the Coldstream Guards.

January 9th, at Colchester, aged 57, William Byass, Esq., Surgeon, late of Worthing.

January 14th, in Portland Road, aged 56, John Pratt, Esq., Surgeon.

BOOKS RECEIVED.

Dissertation on Scientific Nomenclature, Medical and General, &c. By R. G. Mayne, M.D., Surgeon to the Leeds Lock Hospital. London: Churchill. 1849. 8vo. pp. 82.

Demonstrations of Anatomy, being a Guide to the Knowledge of the Human Body by Dissection. By George Viner Ellis, jun., Professor of Anatomy in University College, London. Second edition. London: Taylor, Walton and Maberly. 1849. 8vo. pp. 464.

An Essay on the Cerebral Affections occurring most commonly in Infancy and Childhood: &c. By Valentine Duke, M.D., Fellow of the Royal College of Surgeons in Ireland, &c., &c. Dublin: Fannin and Co. 1849. 8vo. pp. 90.

A Sketch of a Popular and a Novel Treatment for Diarrhœa, Dysentery, and English and Asiatic Cholera. By Edmund Skiers, M.D., &c. &c. London: Highley. 1849. 8vo. pp. 91.

The Retrospect of Medicine. Edited by W. Braithwaite, &c., Vol. xviii., July to December, 1848. London: Simpkin and Marshall. 1848. pp. 468.

The Half-Yearly Abstract of the Medical Sciences, &c. Edited by W. H. Ranking, M.D., Cantab., &c. Vol. viii., July to December, 1848. London: Churchill. 1849. pp. 424.

TO CORRESPONDENTS.

Communications have been received from Mr. Spooner; the Birmingham Pathological Society; Dr. Radclyffe Hall; Mr. J. S. Bartram; Mr. G. M. Humphry; Mr. L. F. Cumming.

The General Medical Annuity Relief Fund.—We regret that we are unable to insert the address in behalf of this Fund in the present number. We shall hope to find room for it in our next.

PROVINCIAL MEDICAL & SURGICAL JOURNAL.

A COURSE OF LECTURES ON SURGERY,

DELIVERED IN THE
MEDICAL SCHOOL OF CAMBRIDGE.

By GEORGE MURRAY HUMPHRY, Esq., Downing
College, Surgeon to Addenbrooke's Hospital.

LECTURE II.

Destructive Inflammation; Changes in Vessels, Blood and Tissues, may be confined to any one, but generally occurs in them all; Effusions of Serum, Lymph, Pus, Colouring Matter of Blood, Pigment; Influence of Nervous System on Inflammation; Inflammation most vigorous in strong Persons, most easily excited in weak Persons and in loose Tissues; Symptoms of Inflammation; Pain, Cause of, Circumstances under which it Varies, Effect of Pressure; increased Heat, Cause of; Redness; Swelling; Alteration or Suspension of Function; Variation of Symptoms and Effects of Inflammation.

The condition of active congestion, or the first stage of inflammation, I described in the last lecture to consist in a mere exaltation of natural forces, often occurring to effect some desirable end, and to be regarded as morbid only when it exists without a sufficient natural exciting cause. When the stimulus is removed, the hyperæmic state commonly soon subsides, the circulation becomes more tranquil, and the vessels resume their usual size. Sometimes it ceases suddenly, an exhalation of serum taking place from the capillary vessels, which seems to be somewhat of the same kind as the critical sweat in fever.

If the exciting cause be continued, the phenomena of destructive inflammation, or inflammation strictly so called, probably begin to exhibit themselves; the action ceases to consist simply in an exaggeration of natural processes, for other changes more clearly of a morbid nature are observed. One of the earliest and most remarkable of these is the adhesion of the red globules, which, instead of floating separately and quickly in the middle of the capillary streams, begin to stick together, and to the sides of the vessels, forming by their agglomeration little masses, which more or less retard the current. Soon their connection with one another is so close, that they seem to have lost their individuality, and to become fused. Some of the colouring matter may be, at the same time, dissolved out of them, and mixed with the serum. The distended vessels, which before had tightly embraced their

contents, become relaxed, the circulation is carried on more slowly through them, the motion of the blood becomes irregular, oscillating or completely stopping. At the same time that this retardation or stoppage of the flow of blood is taking place in the centre of the inflamed part, the circulation may be still maintained with preternatural rapidity in the circumference. If the inflammation ceases when matters are in this condition, the globules again separate from one another, shewing that their fusion had been but apparent, the stagnant blood begins to oscillate again, and yielding to the *vis a tergo*, moves forward. The vessels resume their natural size, and the inflammation is said to terminate by resolution.

The increased attraction of the red globules for one another, may be observed in the blood which has been drawn from an inflamed part, and is so characteristic a sign of the disease, that the quick adhesion of the globules into rolls and masses, in a drop of blood placed under the microscope, is, of itself, sufficient evidence of the existence of inflammation. The mottled appearance of inflamed blood when spread over a wide surface, caused by this peculiar change in its globules, did not escape the observation of John Hunter, who remarks that the "red blood attracts itself forming spots of red."

The other changes occurring in inflamed blood are a diminution in the number of the red globules, an increase in the white globules, and a proportionate increase in the quantity of the fibrin, which has undergone certain alterations in its qualities. Its specific gravity is less, and its great disposition to coagulate and become transformed into tissue, proves it to be endued with higher vitality than usual. The fibrin of inflammatory venous blood is also insoluble in nitrate of potash, in which respect it resembles the fibrin of arterial blood.

In what relation these several changes stand to one another, is not very certain. It may be that the unusual formation of white globules is taking place to supply the deficiency of the red globules, which, on the other hand, are undergoing rapid transformation into fibrin, possessing great force of organization. The process still seems to consist, in part at least, in an exaltation of the natural forces, but it takes place in a disorderly manner, some of the changes being out of proportion to the others, some are of a new or morbid nature, and the whole is uncalled for by the existence of any natural stimulus of nutrition. Far

from there being an increased demand on the part of the tissues to call forth such rapid formation of highly-wrought fibrin, their nutritive powers are commonly weakened in consequence of the existence of the inflammation, for we shall find as we proceed, that the impairment of the nutritive energies of the tissues is one of the most constant and most important effects of the second stage of inflammation. It must be remembered, too, that this modified fibrin is ill fitted to supply the material for healthy nutrition, in proportion to its deviation from the ordinary or healthy state. The perfection of nutrition depends upon the due relation between the coagulating property of the fibrin, and the assimilative influence of the tissues, and the increase in the independent force of organization of the fibrin, necessarily renders it less amenable to such influence, particularly when the nutritive energies of the part are weakened by the inflammation. Adhesions, thickenings, and a variety of new formations, are the consequence of this disordered state of the nutritive functions; the altered fibrin bids defiance to the laws of nutrition, and uncontrolled, or but little controlled, by the weakened assimilative forces of the tissues among which it is effused, coagulates and becomes developed into structures, which have no exact counterpart in the natural condition of the body.

While these changes are going on in the blood, the dilated and relaxed condition of the vessels permits the transudation through them of the constituents of the liquor sanguinis, in greater quantity than natural, which takes place probably in consequence of the altered mechanical condition of the parts concerned in the circulation. The minute vessels are preternaturally distended, and are beginning to lose the proportionate increase of those forces, of whatever kind they be, which had been maintained during the first stage of the inflammation, by which the current was accelerated in them, and the filtration of the constituents of the blood through their walls regulated. At the same time the pressure of the blood upon their stretched and weakened walls has undergone no diminution, because the excited action in the adjacent vessels is continued, and the force of the heart's pulsation is as great as ever. It is no wonder, therefore, that their contents escape in preternatural quantities.

The serum first escapes, and passing from point to point in the interstices of the areolar tissue, may extend to a considerable distance, causing, perhaps, œdema in the whole limb, of which a small part only is inflamed. This occurs most largely in loose structures, and in weak persons. The serum carries with it the saline ingredients of the blood. The filtration through the walls of the vessels of the serum and salts before the other constituents of the blood, accords with the results of experiments made to test the permeability of animal membranes, for it is found that water with saline matters dissolved in it will pass through these structures more quickly than when it is mixed with viscid, gummy, or albuminous substances.

Some of the fibrin soon follows, and becomes diffused in the adjacent areolar tissue, but does not travel far, because it soon coagulates, and evinces its tendency to organization by the commencement of

cell-formation in this unnatural position. A quantity of cells called exudation-corpuscles are formed in the interstices of the tissues, and these cells originating on the exterior of the vessels, often resemble very closely the pale corpuscles which are accumulating in such abundance within them; perhaps they are of the same kind, having undergone some little change, in consequence of their position. However this may be, the coagulation of the effused and altered fibrin, or lymph, as it is now called, blocks up the interstices of the areolar tissue, and gives rise to an indurated condition of the inflamed part. By further development it is sometimes transformed into a structure nearly resembling the areolar. As the inflammation proceeds, some of the fibrin, still further modified by the morbid process, is formed into round or oval granular corpuscles, differing from the exudation cells in their appearance, but more particularly in their inability to undergo any further transformation into tissue; they stand, therefore, in the same relation as foreign bodies. These corpuscles floating in the liquor sanguinis, constitute pus, and this pus enclosed in the previously effused and coagulated lymph, is called an abscess. To these effusions of serum, lymph, and pus, I shall again revert at greater length.

I have said that during inflammation the red corpuscles seem to lose their individuality, and the colouring matter dissolved out of them, and mixing with the serum, may escape through the walls of the vessels. Occasionally the red corpuscles themselves pass through the distended or lacerated vessels, and lodge in the interstices of the tissues. When either the colouring matter or the corpuscles have thus escaped from the vessels, the inflamed part presents a mottled-red hue, and the colour cannot be removed by pressure, as it may be when it depends only on the greater quantity of blood in the vessels. This effect of inflammation varies much in different cases; it takes place most readily in persons advanced in life, or of feeble or disordered constitution. You have probably observed how frequently the pus evacuated from the abscesses of such persons is of a red colour. Sometimes the colour becomes set, and gives rise to those brown or fawn-coloured spots and streaks which mark the seat of former inflammation, or, perhaps, of scorching, in the legs of old people.

The spots of darker hue occasionally found, and looking as if the skin had been stained with nitrate of silver, seem to result from the deposit of pigment caused by inflammation; they are commonly permanent, the colouring material not being again absorbed. The track of an old sinus is sometimes stained of a dark colour in this way, and after chronic inflammation of the bowels, the mucous membrane of the intestinal canal is occasionally covered with minute black spots, looking as if soot had been sprinkled over it.

Finally, the texture of the inflamed part undergoes alterations, independently of those caused by the effusion of new products into its interstices. The changes, dependent, not simply on the altered qualities of the blood, but in part the effect of an impairment of the vital powers of the tissues, produced by the inflammation,

are,—first, diminution of nutritive or reparative energy, associated with preternatural rapidity of dissolution, giving rise to atrophy, softening, interstitial absorption; and, secondly, loss of vitality or death of the part, causing ulceration or mortification, according to the mode in which it takes place, whether piecemeal, or *en masse*.

Such are the more important changes which mark the second stage of inflammation:—Continued distension, but lessened activity, of the minute vessels; diminution in the number and loss of the repulsive qualities of the red particles; increase of the number of white globules; increased quantity and altered quality of fibrine, and impairment of the nutritive forces of the tissues.

You see, therefore, that the inflammatory process is not confined to any one of the agents of nutrition,—to the blood, the vessels, or the textures, but that it usually involves them all, in a greater or less degree. I do not mean to say that it is essential to the existence of the process that all three should share in it; forasmuch as it may occur in the blood alone, without involving either vessels or textures, and it may be present in textures which have neither vessels nor red blood supplied to them,—that is to say, the phenomena of inflammation peculiar to each of the three great agents in nutrition may occur in one alone, without either of the others participating in them. For instance, the adhesion of the globules, the alteration in the qualities of the fibrin, and the formation of pus, may take place in coagula, removed from the influence of the capillary system; and the evidences of inflammation, effusions of lymph and pus, softening, ulceration, and mortification, may be observed in the substance of the cornea, which has neither vessels nor red blood. These changes in the cornea are, it is true, commonly associated with inflammatory disturbance of the conjunctival and sclerotic vessels, which supply the materials of nutrition to that texture, but they sometimes exist without any such increase of vascularity, and are often the precursors and cause of that inflammation of the surrounding tunics, on which they are supposed to depend. Again, the excited action of vessels, existing and continuing for a time, without any other concomitant inflammatory symptom, is so ordinary an occurrence, as scarcely to attract notice. This occasional limitation of the effects of inflammation to each of the three agents commonly participating in it, is of much interest, and clearly shews that to be a very narrow and mistaken description of the process, which represents it as consisting merely or chiefly in an altered condition of the vessels. To obtain a right apprehension of the inflammatory process, it is necessary to take a more comprehensive survey of the changes which accompany it than such a description would induce, and to regard it as consisting in an altered or morbid condition of blood-vessels and textures, commencing in either, but commonly involving them all.

Upon what this morbid condition actually depends, by what influence the adhesion of the red globules, the dilatation of the vessels, and the changes in the textures, are produced, and how these effects are related to one another; what, in short, is the *rationale*

of process, we are at present unable to say. In the same sense that we use the terms life, assimilation, &c., to express the unknown forces whereby certain effects are produced, so must we be content to signify, by the word inflammation, that equally recondite influence which gives rise to the various phenomena indicating its presence.

I have thus far made no allusion to the part which the nervous system plays in the processes of inflammation; that it does exert some influence can scarcely be doubted, but as the connection between the nervous system and nutrition are at present but imperfectly understood, we must not expect to arrive at any very clear ideas of the mode of operation of nervous agencies in the production or modification of inflammation. The existence of animals and textures, in which no traces of nerve-structure can be found, is, perhaps, sufficient to shew that nervous influence is not essential to nutrition; but that a nervous system, whenever present, does exert an important controlling or regulating influence upon nutrition, is equally proved, by the numerous instances in which parts have been unable to maintain their natural condition, when deprived of nervous agency. The wasting of limbs paralysed as to motion, by disease or injury of the spinal cord,—their more rapid wasting and liability to inflammation, ulceration, and mortification, when the sensitive influence is in addition suspended,—the destructive inflammation of the eye, consequent on division of the fifth pair of nerves, which is said to follow most rapidly if it be made in front of the Gasserian ganglion, so that the sympathetic filaments are involved in it, seem to show that the three kinds of nerves, the sensory, motor, and sympathetic, are alike capable of exerting their influence on nutrition. The well-known effect of nervous agency in controlling nutrition is also in favour of the same view.

The inflammatory process being but a modification of nutrition, is probably in like manner, and to the same extent, subject to nervous influence. Indeed, the evidence of the operation of nervous agency in nutrition derived from the experiments above quoted, is founded chiefly upon the observation of the inflammatory disturbance consequent on its suspension. Many examples of the same kind might be adduced, but I will mention only that well-known one of the inflammation occasioned in a paralytic limb by water, heated to a temperature insufficient to injure the opposite sound extremity. If such results be shown to follow the *suspension* of nervous influence, it is not improbable that disturbances of an inflammatory kind may be produced also by an extraordinary *accession* of the same, from excitement or other cause. The effect of the emotions upon the circulation through the heart and capillary system is obvious enough, and would no doubt operate prejudicially upon a part already inflamed. That nervous irritation, as it is called, sometimes induces, as well as contributes to, the maintenance of inflammation, is rendered highly probable, if not proved, by the sympathetic affections, which are of such constant occurrence. I know not in what other way to explain the attacks of inflammation of the brain consequent on teething and worms in

the bowels, or a still better instance, the frequent association of inflammation of the testicle with gonorrhœa, than by supposing that the irritation is communicated from one part to the other through the medium of the nervous system.

Possibly the extension of inflammation from point to point along a surface, and from one tissue to another in its immediate vicinity, may be in some measure due to the radiation of nervous irritation occasioned by it, in addition to some direct influence of an assimilative kind upon the surrounding nutritive forces, inducing in them a change similar to that which exists in the part first affected.

The inflammatory being a modification of the nutritive and vascular processes, is carried on most actively where they are in greatest force,—where the vascular system rather predominates, in strong and plethoric persons, and in textures rich in blood-vessels. Its activity and the well-marked character of its products are a fair criterion of the vital energy of the individual and of the organ in which it occurs. On the other hand, where the vital powers are feeble, it is languid in its progress and its products are ill formed. Hence the slight amount of inflammation which is sometimes observed to follow serious lesions of important organs, which have been attended with great constitutional depression, and the fact that vesication does not follow the application of a blister when the patient is falling into a state of collapse.

Although the disturbance of the nutritive and circulatory processes attending inflammation, is most clearly developed where those processes are usually conducted with the greatest energy, it is nevertheless, most easily excited, and its effects are most destructive, in the tissues of low vital force, in feeble persons and in the lower extremities—in the parts last developed and most distant from the centre of the body. Hence the frequent occurrence of troublesome sores and mortification in the lower extremities of old persons, the rapid formation of bed-sores in paralysed limbs, and the frequent occurrence of ulcers and other inflammatory affections in parts which have been weakened by disease or severe injury. A considerable number of persons whose health is broken and strength failing under the effects of long-continued and wasting disorders, are carried off by some attack of inflammation of the skin, lungs, liver, or other parts, which runs into its most destructive stages before we are well aware of its existence. Patients with cancerous affections of the breast, rectum, or œsophagus, often die suddenly and unexpectedly, on having caught cold, which under ordinary circumstances would soon have passed away, but in their enfeebled state, is quickly followed by pneumonia or gangrene of the lung.

Cæteris paribus, tissues of loose structure are most liable to inflammation. It is of frequent occurrence, and soon runs on to suppuration, in the areolar structure, especially in that of the axilla, around the anus, and in other similar situations. It affects the back of the hand and foot, more readily than the sole and palm; and erysipelas of the face generally commences, and spreads most quickly, in the fine loose skin about the eyelids, bridge of the nose, cheeks, and

ears, and does not extend, except in severe cases, to the tougher parts of the integument from which the hair grows—the lips, chin, and scalp.

Let us consider briefly the local symptoms of inflammation, as they are presented to us in case of inflammation of the finger, originating, it may be, in a prick or slight wound. The first indication of commencing mischief is pain, of an aching or burning character; it keeps the patient awake during the night, and extends from the finger up the arm to the shoulder. In the morning the finger is found to be red, somewhat swollen, and hotter than natural; the pulse at the wrist beats with greater force than on the opposite side; and the veins of the finger and hand are turgid. The symptoms increase, more particularly the swelling, which becomes firm at the centre of the inflammation, but remains soft in the circumference, and is diffused over a considerable part of the limb. By and by the pain alters in character, becoming heavy and throbbing, even more insufferable than before. In the centre of the hard swelling, a soft spot is discovered, from which we infer that suppuration has commenced; the soft spot increases in size, so that the presence of fluid, or fluctuation, is distinguishable by the touch; at the same time the surrounding induration and cedematous swelling begin to diminish, as though the disease were concentrating its forces upon the centre, where the pus is being formed. Gradually the parts intervening between it and the surface become thinner, and are raised by the pressure of the pus, the white colour of which may be seen through them. Ultimately they give way, affording a vent to the pus, and much relief to the patient. It seems as though the object of the inflammation were now accomplished, for it gradually subsides, its effects are removed, the discharge soon ceases, the orifice is closed, and the hand is restored to its natural condition.

Such is the ordinary course of an attack of phlegmonous inflammation, or inflammation of the cellular tissue of the hand, when the progress of the affection is quick, and the formation of an abscess takes place, the four symptoms which most especially attract our attention being pain, redness, heat, and swelling. Of these, the pain is generally the precursor, and cannot, therefore, be a consequence of any of the others. It cannot depend, as it has been supposed to do, upon the pressure of the nerves between the distended vessels, inasmuch as it sometimes exists, to a severe degree, before the vascular disturbance has commenced. It is more probably owing to some altered condition of the nerve-fibres, which share the disease in common with the other tissues involved. It is proportionate to the natural sensibility of the patient, and of the part affected. It is severe in inflammation of the skin, particularly of the fingers, and very acute when the enveloping serous membranes of the internal organs are affected, being of a more dull heavy character when their parenchyma or lining mucous membrane is attacked.

Pain is the general term used to express the exaggeration or alteration of the sensation of the inflamed parts; and as different parts have their peculiar sensations, so does the character of the pain in inflammation

vary in a similar manner. Inflammation of the eye, more particularly when it affects the retina, is attended with acute sensitiveness and intolerance of light, and with the appearance of flashes, stars, and scintillations of various kinds. And corresponding morbid acuteness, as well as erroneous impressions of sound, smell, and taste, are observed in inflammation of the ear, the olfactory and gustatory organs.

In the well-ordered constitution, the pain is a fair measure of the activity of the inflammation, but in nervous and sensitive patients, and in persons out of health, it is often very disproportionate to the real disease, and is sometimes so acute that we may be induced to resort to treatment of unnecessary and injurious severity, or, on the other hand, may overlook the inflammatory part of the disorder, and imagine the affection to be entirely of a hysterical nature. This frequently happens in young women, whose nervous system is particularly sensitive. In such persons, a slight attack of inflammation of a joint is often attended with excessive pain and tenderness, which are not confined to the part immediately affected, but extend to a considerable distance from it, perhaps all over the limb. These cases of inflamed joints, in which the pain is disproportionate to the other signs of inflammation, are very difficult to cure; the affection lingers on from week to week, and month to month, bidding defiance to one mode of treatment after another. Sometimes the inflammatory condition subsides altogether, and leaves behind merely a state of preternatural sensibility; the joint continues painful and tender, so that slight blows cause severe suffering, felt for a long time; and a little more exertion than usual in the day is followed by a sleepless night, in consequence of the pain. You have seen several cases of this affection of the knee-joint, lately under treatment at the hospital; in all of them pain and tenderness were the prominent symptoms, in some of them the feeling of crepitation in the joint was greater than natural, and in a few there was slight swelling in the evening. In addition to the tonic regimen, or constitutional treatment, which the particular symptoms seemed to require, more benefit was derived from pressure, by means of adhesive plaster, or plaster containing opium, than from any other local application.

Secondly. The pain of inflammation is generally greatest in dense resisting structures—as the fibrous and serous membranes, bones, the testicle, and the eye-ball.

Thirdly. Pain is proportionate to the activity of the inflammation. You will sometimes be surprised at the slight amount of suffering caused by extensive and destructive inflammatory affections, of a languid character, in scrofulous persons. The pain varies also with the stage of the inflammation, being dull, heavy, or throbbing, when suppuration begins, and very severe when the inflammation is passing into ulceration and mortification. This is more particularly the case in phagedenic ulceration, and when mortification supervenes quickly on the occurrence of inflammation, as in traumatic gangrene, and some other cases to be described in treating of mortification.

I have said that the pain of inflammation depends

upon a deranged condition of the nerves rather than upon the vascular fullness of the part, because the pain often occurs before the other symptoms have set in. Nevertheless, there can be no doubt that it is materially increased by the pressure of the tender nerves between the distended vessels, as well as by the general stretching of the part, the resistance of some tissues and the yielding of others; and it may occasionally be diminished very much by the expulsion of the blood from the inflamed part, and the support afforded by well regulated pressure. In this way great and sudden relief may sometimes be obtained from the severe pain of acute inflammation. Patients have been able to walk about immediately after the application of pressure to an inflamed testicle, the pain of which had before been almost intolerable, and the disease has thus been cured. To effect this the pressure must be steady, uniform and continued, so as to support the distended vessels and the stretched tissues, without exerting violence at any particular part; and unless the pain be relieved in a short time, the pressure should be removed, for the continuance of the pain is a sure sign that the treatment is doing no good, and it may be productive of much mischief.

Although pain thus occasionally admits of much relief from uniform external pressure, it is greatly aggravated by collections of pus within the part, causing stretching of the inflamed and resisting textures which surround the abscess. Many of you have probably experienced the immediate relief afforded by the opening of a small subcutaneous abscess or boil, over which the skin was inflamed and tense, and you may conceive how dreadful must be the agony of acute suppuration going on in the interior of the eye-ball.

The increased heat of the inflamed part, though not so great as the altered sensations of the patient would imply, is, nevertheless, appreciable by the thermometer. The average heat of the body ranges from about 98° to 100° , but in fever it has been known to rise to 107° ; and Hunter's well-known experiment is sufficient illustration of the rise of temperature in the inflamed part. Having tapped a hydrocele, and introduced a thermometer through the trocar, he found the heat to be 92° ; on a repetition of the experiment next day, when the inflammation had set in, the thermometer rose to $98\frac{1}{4}^{\circ}$, shewing an increase of $6\frac{3}{4}^{\circ}$. This increase of temperature in the inflamed part, is due to the preternatural rapidity of those changes in the blood and textures upon which the natural heat of the body depends;—to the greater afflux of arterial blood, the quick formation of fibrin, &c., during which, oxygen is combined and heat generated. A sort of combustion is going on, of the same kind as that which usually takes place in the body, but with increased rapidity. The heat of an inflamed part within reach of the thermometer is not very likely to exceed that of the blood in the centre of the body, but it is possible that this may occur when an internal organ is the seat of acute inflammation.

The redness attendant on inflammation depends, as I have already explained, upon the dilated vessels admitting a greater number of red corpuscles, which find their way into capillary tubes in sufficient numbers

to become visible. The shade of colour is bright when the inflammation is active, dull or bluish when it is sluggish and chronic. The swelling results in part from the distended condition of the vessels, but chiefly from the effusion of the constituents of the blood into the surrounding tissues; it is, therefore, greatest in parts where looseness of texture offers least resistance to the passage of these fluids into them—as the scrotum, the neighbourhood of the eyes, and the face. It is at first soft, being occasioned by the presence of serum, which extends to a considerable distance from the inflamed part; then it becomes firm in the middle, in consequence of the effusion and coagulation of fibrin or lymph; and, thirdly, the existence of a soft central swelling, with an indurated circumference, is a tolerably sure sign of the presence of pus.

I must not omit to mention another important symptom and effect of inflammation, which is nearly allied to the alteration or suspension of nutrition,—I mean, the alteration or suspension of function. The inflamed brain either acts in a disorderly manner, giving rise to erroneous ideas and convulsive movements, or it ceases to convey impressions to the mind, and to exercise volitional sway over the muscular system; and an inflamed muscle refuses obedience to voluntary impulses—it cannot act. The alteration and suspension of secretion is still more obvious, and constitutes one of the symptoms on which the physician most relies, in forming his diagnosis of the inflammation of an internal organ.

I have described to you the symptoms of inflammation, as they commonly occur, illustrating them by the instance of inflammation of the finger, which may be taken as a fair specimen of the disorder in its complete or fully developed condition, where its chief symptoms are presented to our observation, but I should greatly mislead you if I were to induce you to imagine that this protean disorder always presents the same symptoms, or follows the same course. Any, or indeed all, of the above-mentioned symptoms, may be absent, and we are sometimes cognizant of the existence of the process only by witnessing its effects; still, more frequently, the inflammation is seated in a spot concealed from our view, so that we can gain no information respecting the redness, the heat, and the swelling, and have to take as our guide the pain, the least uncertain of all the symptoms, because it is the least likely to be proportionate to the severity of the disease, and because it is communicated to us through the medium of the patient.

In its effects also, inflammation is no less variable than in its symptoms; in one case effusion, in another, ulceration, takes the lead, and in a third the invasion of the disease is quickly followed by mortification, without our being able to offer an explanation of the particular result in either case. I cannot present a more striking illustration of the numerous forms in which inflammation may occur in a single tissue, than by directing your attention to the diseases of the skin. A chilblain, carbuncle, erysipelas, and lepra, are all inflammatory affections, yet how greatly do they differ from one another, and how little do we know of the causes upon which these differences depend. Equally

unintelligible, in the present state of our knowledge, are those peculiar changes in the blood, dependent (as we suppose,) upon the influence of subtle poisons, which attach to inflammation the distinctive characters of scarlatina, measles, small-pox, and syphilis.

THE

CONTAGION OF ASIATIC CHOLERA.*

By E. O. SPOONER, Esq., Blandford.

If we examine the official reports of the cholera in Great Britain for the *first nine weeks*, from September 28th to December 1st, we shall find the number of cases 1,590, of which 741 have died. Of these cases the metropolis gives 413, and the deaths 225. The whole number of cases reported at this period of more than two months, after the first invasion, in the remainder of England and Wales, is only 148, and the deaths 77. The proportion is more than 3 to 1; yet, when we further take into consideration that the metropolis contains two millions and a quarter of inhabitants, while fifteen millions inhabit the cities and villages of England and Wales, (a large number living in towns far worse than the metropolitan district in point of sanitary arrangements,) we must be still more struck with the disproportionate mortality nine weeks after we had been told the epidemic influence had reached the shores of England!

In Scotland, or rather in about seven localities there, are reported in the same time 1,011 cases and 439 deaths, yet, all Scotland does not number three millions. Here again we have 3 to 1 against Scotland. If we take into account the number of pest vessels which have entered the mouth of the Thames and the Firth of Forth from the infected ports on the continent, *we shall be able to explain this anomaly.*

Each focus of contagion has its own radius. The intercourse of the Firth of Forth soon reaches Glasgow and Dumfries. The first nine weeks of cholera in England, however, clearly show that for the most part, those places only had been then visited which have *primarily* had a large tonnage of *northern shipping.*

The *secondary spread* of cholera by inland communication with our own affected ports has not yet penetrated very far into the interior of the country. A tramp arrives at Hertford or Reading, and originates a few cases; or a family with the disease about them, migrate from London to Offchurch, in the neighbourhood of Leamington, and, with indecent haste, Leamington is reported by the Board of Health to be cholera smitten.

Indignant contradictions to these misstatements are common enough, and it is scarcely worth while to say that Portland, some eight weeks ago, was reported in the cholera list.

* Continued from page 37.

The not uncommon occurrence of the death of a child of three years old, after a few hours illness, induced the Board to make this evidently erroneous statement. They must at that time have been extremely anxious for country cholera cases to put this down as one of Asiatic cholera. They have not been able to report a case there since. It has been evidently the object of the Board, in order to prop up their theory of the local origin of cholera from defective sanitary arrangements, to make it appear that here, there, and everywhere in England it was going to shew itself. The laws of its contagion refuse to bend themselves to their sanitary theories, and country cholera cases in England, after three months importations, have hitherto been rare. The next three months, however, will reverse the picture.

I have already observed that the non-contagion of cholera, though it has been puffed off *pro bono publico* in the companion to the "British Almanack," as a "most blessed" discovery of the sanitary commission, was the general belief of the Indian surgeons previous to 1824. In 1824, Dr. Krabinski, an Armenian physician, residing at Tiflis, in a letter addressed to the Archbishop of the Armenian Church, propounds the same dogma. "This disease is not contagious, like the plague and other diseases." He had seen much of the disease, both in India and Persia, but in the warmer climates of the east so rapid is the diffusion of contagion, that the spokes of its chariot wheels are not visible. Dr. Reumann, however, in the same year, published for the Russian Government two volumes of valuable reports on the "Progress of Cholera from 1817 to 1823, when it appeared at Astrachan." He was one of the most distinguished of Russian physicians, and with the electric scrutiny of a logical mind, he detected what was invisible to Krabinski. He says,—“We deem it, nevertheless, to be contagious, and there is no doubt but that it was brought by the merchandize and people in the boats to Astrachan, yet it is not so infectious as the plague.” Questions of this controverted character are not to be settled on the mere dicta of authorities, and though the Sanitary Commission, and the Board of Health, have adopted the Krabinski dogma, we must be permitted to enquire into the new advices received at the foreign office upon which their conclusions are grounded.

Let us examine the most recent, published in the Appendix to the second report of the Sanitary Commission. Here we find diametrically conflicting testimony; one of the deponents is, however, merely a British Vice-Consul; the other, an experienced British physician. Mr. Vice-Consul Bassam, of Mossul, in a despatch dated January, 1848, says,—“From what I have seen of this disease it does not appear to be in the least degree contagious, and scarcely, if at all, infectious, unless, perhaps, where many sick are congregated together, as in the wards of a hospital; in

fact, I should consider it as an almost true epidemic, such as the influenza which has prevailed here since the last cholera disappeared.” Quite a Coryphæus in the favourite doctrines of Gwydyr House is this Mr. Vice-Consul Bassam, the eminent professional authority at Mossul! Alas! medical men very seldom obtain the Consular or Vice-Consular dignity. Her Majesty's Consul at Archangel is more modest, and requested Dr. Mackenzie, Staff Surgeon, to answer the question. He says, very distinctly and pointedly, —“The majority of facts collected during the present visitation of the cholera confirm the opinion that the disease spreads from person to person, through the medium of the air, and there is every probability that the principle of infection finds its way into the system through these different media,—viz., the respiratory organs, the digestive organs, and the skin” Such is some of the evidence of “the gradual abandonment of the opinion that the propagation of epidemic disease is mainly dependent on a specific contagion emanating from the bodies of the sick!” Thus, we see then, the most recent advices do not bear out the conclusion announced with so much emphasis by the Sanitary Commission, yet their epitomist, in the “Companion to the Almanack,” (I suppose one of themselves,) bursts into the rhapsody,—“Blessed discovery!” “It is impossible to over-rate the importance of this discovery.” He adds, in the same *Io pæan* style,—“The non-contagious character of cholera is now then considered sufficiently established, and how many blessings follow in the rear of that one great blessing.” We cannot, for the life of us, understand the consolation which the public can receive from knowing that they may at any moment, in any part of England, breathe this “poisonous gas emitted under certain conditions of heat and moisture, from decaying animal and vegetable matter, unduly exposed to its influence;” that they may meet with it “going up one side of a street,” or “waiting for the opening of a door before it enters the house!” This seems very sorry comfort indeed, though it may be deemed a most wonderful discovery! One would imagine from Dr. Parkes, that the safest place was the bedside of the sick, rubbing their cramped limbs, or emptying their close stools, for “not one of these hospital attendants,” says he, “were attacked.” “The medical officers were constantly on duty, yet enjoyed the same immunity.”

They were unsusceptible enough to escape such a subtle enemy as the epidemic atmospheric influence, and yet we are told their escape proves the disease non-contagious! As reasonably might we conclude that the well-seasoned nurses of our scarlet-fever and small-pox patients, who do not catch the disorder, prove these diseases to be non-contagious. *The mild and benign form of cholera is a simple diarrhœa, which may be quite as effectual as the modified form of small-pox, induced by inoculation or vaccination. A*

slight redness in the throat, and a scarcely-noticed rash on the skin, will for ever render a person unsusceptible of the most malignant exhalations of scarlet-fever. Secondary attacks occasionally occur; but the majority of mankind, if they have passed through the milder forms of either of these contagious diseases, are thenceforward *contagion-proof*.

The law is less universal with cholera, but it will be found sufficiently general to solve the enigma of the *occasional immunity* of nurses and *medical men* when in the closest attendance upon the sick. But that this immunity is only *occasional*, dependent on natural insusceptibility or previous seasoning, has been proved by our best authorities.

Drs. Russel and Barry, in their able report on the cholera of Russia in 1831, make the following statement respecting St. Petersburg:—"The number of medical men and hospital attendants attacked with cholera during the present epidemic in proportion to the whole employed, has been beyond all comparison greater than in India, under similar circumstances. Twenty-five medical men have been already seized, and nine have died out of two hundred and sixty." Notwithstanding the early attention to the first symptoms which medical men and hospital nurses receive, *many deaths have already been recorded in England and Scotland during the present epidemic. The number of mild attacks, of course, are unknown; they are considered simple cases of diarrhoea; but they are, in fact, mild attacks of cholera.*

We are glad to find the eyes of the medical profession in Scotland and in Ireland are beginning to open to some of the fallacies of the Board of Health and the Sanitary Commission, and we are gratified to know that a man of Dr. Simpson's acuteness has personally investigated the origin of cholera at Newhaven, though his coachman narrowly escaped the formidable effects of the contagion. It is true four of the nurses of the Edinburgh Cholera Hospital were within twenty-four hours (according to Dr. Sutherland,) poisoned by the emanations of the crowded wards. Three of the four died of Asiatic cholera; but Dr. Sutherland says very coolly "we don't call this contagion!" "I warned them of their danger from the bad smell I detected," and the Sanitary Commissioners have testified to the "general immunity of nurses and other attendants on the affected!!"

One of the most recent and graphic descriptions of cholera has been afforded by Mr. Thom, in his Report of the causes, character, and treatment, of the spasmodic cholera in H.M. 86th Regiment, at Kurrachee. Among the arguments brought forward by this gentleman, occurs the following passage:—"It was equally apparent that there was nothing contagious in the nature of the disease, *for instead of a few cases appearing first, and the disease gradually spreading*, it suddenly burst forth in a few hours in every European regiment,

whether in camp or barracks,—in every tent, and in every house; and it was at its acme in forty-eight hours after, when, instead of spreading further, it gradually declined. Now, it appears that for some days or even weeks, A FEW CASES HAD APPEARED IN THE NATIVE TOWN OF KURRACHEE, but there, about the same period, the malady became suddenly general over the whole place." Now, it appears the few cases appearing for some weeks within the town, were evidently the first *germs of the disease*, which atmospheric causes rapidly ripened and diffused, and entirely do away with the inference drawn from *apparent suddenness* of the general attack. But taking for granted the fact related, that a "few hours were sufficient to spread the disease in all the regiments," we would point out as a complete contradiction to Mr. Thom's deductions respecting the non-contagion of cholera, the circumstances observed in England;—the "few cases occurring first," and "then the disease gradually spreading," is the *universal law of the disease as it has hitherto shewn itself in this country*. The slow progress of the first few weeks of cholera, and the gradual diffusion of the disease at the present time, constitute the very circumstances which Mr. Thom points out as conclusive evidence of contagion. If the argument be a good one as employed by Mr. Thom negatively, it must surely be better still when we find the direct reverse of the picture positively occurring in this country. But the facts are still further explained by Mr. Thom himself. "Long before its visit to Kurrachee," says Mr. Thom, "we heard of its appearance in the Madras Presidency, and subsequently at Poonah, Bombay, and Ahmedabad, Deesa, and finally arriving by the coastward to Scinde, where it first broke out at the sea coast, and from thence gradually extended to Hyderabad and Schwaun."

Now, its gradual advance in the lines of commerce, and its first invasion of the sea-coast of Scinde, are both opposed to the suddenness of the outbreak. The fact is, for a fortnight previous to the arrival of our regiments, the cholera had existed in Kurrachee, in a mild and insidious form. The stagnant atmosphere was loaded with the poison of the pestilence, and no wonder in an Indian climate and in crowded cantonments, the troops were soon rapidly affected. But another remarkable fact which Mr. Thom relates as a proof of its non-contagion, was the comparative escape of the officers. In addition to their being *well fed with animal food*, and better nourished than the men, they were quartered in "houses detached and isolated," and "permitting a free current of air." Can any evidence be more decisive in favour of isolation? If the cause were *wholly* atmospheric, why were not the officers seized as well as the men? They were actually between the two fires,—"*between the 60th regiment and the Sepoys*," both of which suffered severely. Their better nourishment, the isolation, and the

ventilation were the concurrent causes of exemption. The first rendered them less susceptible of contagion, the last two put them out of the reach of infection in such a concentrated form as to produce the disease.

We have read loose statements with regard to the immunity of medical men in India. Putting out of the question the attacks of *diarrhæa*, which we should call *mild cholera*, which were no doubt promptly treated and arrested in the cases of the medical men, we find four out of forty engaged in Scinde, were carried off by the disease. Four out of forty or ten in a hundred is a larger proportion than the number of fatal cases, either in the Sepoy or European regiments. Thus, not only is the fact of the "greater numerical proportion" falling sick with *diarrhæa*, attested by Mr. Thom, but his own statistics clearly prove that the medical officers suffered a greater proportion of mortality than the other officers, and even as great as that of the sepoys, notwithstanding their prompt attention to the first symptoms. This new evidence, then, when carefully sifted, corroborates the statements of Drs. Barry and Russell, whose personal experience, though not so recent, was far more extended. They had witnessed the disease first in the climate of India, where the heat and moisture of the atmosphere combined to render the contagion of cholera most rapidly diffusible and miasmatic, but they added to that experience the most extended observations on the same disease as it appeared in a Russian climate. At St. Petersburg, in 1831, they state, "The number of medical men and hospital attendants attacked with cholera during the present epidemic in proportion to the whole employed, has been beyond all comparison greater than in India under similar circumstances; twenty-five medical men have been already seized, and nine have died, out of two hundred and sixty." The subsequent history of the epidemic in St. Petersburg increased these proportions; while in Paris, where the non-contagious doctrines had taken deep root, the mortality of the medical men was still higher, and even the Prime Minister himself, Casimir Perrier, fell a victim to an insane perambulation of the cholera hospitals, which he took with other officers of State, to assure the public mind that the disease was not contagious. Buonaparte, at Jaffa, was more fortunate, when for similar reasons he breathed for a few minutes a well-ventilated plague-ward of his military hospital.

Anticipating the future spread of the Asiatic cholera throughout the land, when the warm sun of the spring and summer shall ripen the latent germs of this contagion into its acme of malignancy, I cannot but view with some degree of anxiety those non-contagious doctrines which emanate from men in high authority, whose position enables them to influence the opinions of the public as well as a large portion of the profession. Though many books and reports have been written within the last three years on the subject of

cholera, very little has been added to our previous knowledge. Cases of collapse are as uncertain in their result as they were in 1832. The importance of attending to the early symptoms was as clearly taught in that day as it is now; the propriety of ventilation and cleanliness was as universally acknowledged as it is at present. The immediate removal of those attacked with *choleric diarrhæa* into a clean and airy apartment, ought to have formed one of the special directions of our Board of Health. We think that such a plan at Tooting would have mitigated the calamity, but the non-contagious doctrines had unfortunately perverted the mind of the medical attendant, and though he has since changed his views on the subject, a fatal experience has been necessary to remove those errors which men of high position and standing had too carefully propagated.

Since the Asiatic cholera emerged from the confines of Jessore, in 1817, it has not ceased to make its appearance in some quarter or other down to the present time. Thirty-two years of its history have enabled us to track its steps from the extremities of Asia, through the continent of Europe, along the shores of Africa, and even in the New World. From the banks of the Ganges it passed into Burmah and China to the East, while towards the West with equal steps it reached Persia, the shores of the Caspian, the Russian empire, and the various countries of Europe, appearing in America, on its first and last invasion, soon after it had reached the Atlantic ports of Europe. No other disease, besides the small-pox, ever took so wide a range, or continued to exist for so long a period. It possesses the same analogies, in time and space, and unless human ingenuity discover some prophylactic, it bids fair to rival its predecessor in fatality also. It has ever travelled with the measured steps of the human traveller; not with the monsoon, but sometimes against its current;—not with the hurricane, nor with the earthquake. It has not taken any track of volcanic action nor electric movement; it passes toward all points of the compass, irrespective of magnetic or diamagnetic lines of force. In Russia it travelled at the rate of between two and three hundred miles a month, (from 400 to 500 kilometres.) It crosses the Atlantic, taking the line and the mode of conveyance of emigrant ships. It was well observed by the *Quarterly Reviewer* in 1831, that it had "a marvellous penchant for easy travelling." It delights, too, in social intercourse; and in India accompanies marching armies or their camp-followers; and is very fond of grand festivals, whether at Juggernaut or Mecca. But though India had its Juggernaut festivals for ages previous, cholera never broke out among its congregated masses till after the *leaven* of 1817. Our armies had often crossed the peninsula of India, but never had they been decimated by the cholera till the forces of the Marquis of Hastings were very nearly put *hors de*

combat, by marching into the focus of its contagion, in 1818; and though since the death of Mahomet pilgrimages to Mecca have been annually made by multitudes of the Moslem population, cholera never appeared among its caravans till subsequent to its appearance in Persia, in 1819. Can we draw any other conclusion from premises so well defined and universally acknowledged, than that a disease thus portable must be also communicable?

It is universally attributed to *human intercourse*, from the boats of Astrachan, to the tramp lately confined in Hertford gaol, after whose introduction it broke out in three days among the prisoners. Belfast and Offchurch, Leith and Staten Island, tell the same story. It is nowhere bred and multiplied till it has been *first imported*. The tell-tale newspapers constantly reiterate this statement; can anything but a *contagious principle* account for such uniform testimony? Can any disease be portable and reproductive without being contagious? Do we ever hear of the agues produced by the fens of Lincolnshire travelling over the Cotswold Hills? Malarious influence is confined to the localities which generate it; *it is the property of contagion alone to defy all climates*, and such has been the case with the Asiatic cholera, wherever its poisonous *leaven* has been imported. Cesspools and stagnant ditches,—the bogs of Ireland,—the back slums and sewer mouths of London, and Glasgow, and Edinburgh, were all as numerous and uncleansed in 1847 as in 1848, and soup-fed pauper children were crowded in masses then as now, but no pestilential cholera was generated under all the conditions of vegetable and animal putrefaction, in that, or in ten preceding years. The efficient cause was absent; the *contagion* was not imported till the autumn of 1848.

That diseases exist which are *both epidemic and contagious*, cannot be a matter of dispute among scientific men who understand the meaning attached to those terms. If an epidemic disease be defined, as some writers have done, as a disease not capable of being propagated by contagion, and if Asiatic cholera be considered as such an epidemic, it is at once begging the question. We deny *in limine*, the major proposition. The definition is erroneous. Small-pox is *often an epidemic*, and yet is invariably propagated by contagion. Cholera we allow to be an epidemic disease, and its whole history from 1817 to 1849, demonstrates that it is a pestilence which is propagated by contagion, or in other words, that the *emanations from the sick are capable of communicating the same disease to the healthy individual*! Now, small-pox has never been absent from the earth since the time of Mahomet, when it first appears to have commenced its destructive career. Since that early period it has always been found, and though it was once fondly anticipated by those who founded the practice of vaccination, that like the dodo, it would by and by become extinct; the

history of its progress and continuance have hitherto falsified the anticipations of the enthusiastic philanthropist. The “sweating sickness,” and “the black death,” which committed such ravages during the middle ages, have entirely disappeared. They *may have been epidemics* without the contagious property,—without the power of reproducing and perpetuating their kind, and when the conditions of their production ceased they may have died a natural death. It is impossible for us now to settle the question of their contagion upon any satisfactory basis. The facts are wanting on which to build a perfectly satisfactory conclusion. It would have been fortunate for mankind if the cholera had left us equally in the dark.

The epidemic invasion of the Asiatic cholera in 1831, was first reported officially in the first week of December in that year. The last week in March, 1832, (March 29th,) presented the following statistics of the disease:—

Total number of cases	8815
Total number of deaths	3320

This table exhibits the extent to which the disease had extended on its first (generally the most severe,) visitation during the period of four months. The view taken by the Board of Health of that period, as well as by the majority of medical men in England, was, that the disease is contagious. The garments and bed-clothing of the sick were strictly purified if not destroyed, and the communication between the sick and the healthy was as much as possible suspended. No such recommendations have been issued by the present Board of Health, and the community have been taught to believe the whole system of quarantine public and private, national and domestic, quite useless and impracticable.

What has been the result of the new system adopted by the Board of Health now in existence?

The Asiatic cholera began its ravages in the first week of October, 1848. Up to January 27, 1849, *rather less than the same period*, the following results have been registered:—

Total number of cases	10,047
Total number of deaths	4,467

It appears thus pretty clearly, that our present Board of Health have been quite unsuccessful in their plans so far as the arrest or the mitigation of the disease goes. We shall by and by enquire into the sources of their failure. We have had, instead of a diminution of the disease, an actual increase of one fourth during the first four months.

(To be continued.)

ON CERTAIN MORBID CONDITIONS OF THE EPIGASTRIC REGION.

By T. L. WALFORD, Esq., Reading.

(Read at the Reading Pathological Society.)

MR. PRESIDENT AND GENTLEMEN,—

The observations I am about to make relate especially to such an amount and continuance of disorder, as frequently does not prevent the individual from going on with his ordinary duties, yet, existing, constitutes the groundwork of liability to many ordinary ailments, often being the cause why these ordinary ailments do not run through their stages in a short time, or it may be the occasion of their more frequent recurrence than might reasonably be expected.

My object is to point out the precise mode of examination adopted by Dr. Wilson Philip, when examining the liver, to explain the kind of treatment pursued by him, and to call attention to a consequence of protracted indigestion, which forms the basis of that physician's last work, conceiving that his mode of examination is known only to a few, that the kind of treatment he pursues is believed to consist in the administration of ridiculously small doses of mercury, and that no distinct idea exists of the way in which it is believed by Dr. Philip, that consumption does follow as a consequence of protracted indigestion. I regret much that I have not been able to search the works of Dr. Philip, and to extract those parts which he considers proves the effect upon the nervous system from disease in any one organ, and the effect of this induced state of the nervous system, either upon the organ which caused the derangement, or upon some other, whereby the constitutional tendency of that organ would be developed.

It may be stated, as a general proposition, that health is the result of the health of each part combined, consequently when any part has lost its health, the combination is imperfect, and disease is manifested; sooner or later certain other parts become involved. Now, the mode by which the healthy action of one organ is taken cognizance of by all the rest, and the healthy action of all the rest is taken cognizance of by the one, so as to constitute this health, is a subject the consideration of which is deeply interesting; and in proportion as we understand this mode, do we understand the mode in which, when one part becomes diseased, the whole are in consequence at once affected, while certain organs become, after a longer or shorter interval, idiopathically involved; and it is because other parts suffer from disease in any one organ, or parts of an organ, that the selection I have made receives so much importance. The constitutional origin of local diseases has this observation for its basis. It may be further remarked, however, that setting aside those diseases of some organs, which in their effects upon others, disturb their functions mechanically, there are instances of more direct sympathy between one organ and certain others, than between all the rest, this relationship being made sometimes to depend upon age, sex, temperament, &c.

For an ordinary example, take the occurrence of inflammation of the testicles, in an individual suffering from the mumps. Many such instances might be mentioned, and, doubtless, some at once occur to each of you.

By the expression, certain morbid conditions of the epigastric region, I would be understood to mean, the condition of three parts—the pyloric end of the stomach, the liver, (as represented by its left lobe,) and the first bowel. I shall not contend, that the whole of the duodenum is in this region, but that is unimportant. Now, when these parts are not in a normal condition, a state of parts exists, which it is of the greatest importance to recognize and to relieve, even though our assistance may have been sought for a super-added affection. Imagine, for example, that assistance sought for an attack of piles, and, considering piles to be associated with a costive state of the bowels, and both dependent upon inaction of the liver, the importance of looking to the condition of the epigastric region will at once be manifest, especially as the more effectual means of quickly relieving the patient can only be applied after such an examination. Indeed, the preventing of a recurrence of the attack, entirely depends upon such recognition, and this is as much the duty of the medical man, as the obtaining for his patient immediate relief.

In examining, then, the epigastric region, I would describe a state of parts, sometimes discoverable on a physical examination, premising that sometimes only one organ, more frequently two, and at other times all three may be deranged together. I will notice them in the order in which I just mentioned them. *First*, then, the pyloric end of the stomach may have become thickened, and in such a state as to cause great tenderness on pressure. Of course, by the physical examination, I only propose to recognize the tenderness, and thence infer, more or less of thickening. But to find out this tenderness, (bearing in mind it has been slowly called into existence,) it will be desirable to let the patient stand, where the circumstances allow that posture, the part being only thinly covered, and, ascertaining a space, commencing about an inch below the ensiform cartilage, place two or three fingers, at nearly right angles, parallel to the margin of the false ribs on the right side, but leaving an interval of half an inch. Now, a sudden pushing them inwards, when this tenderness exists, will give much pain.

Now, it is stated by Dr. Philip, on the authority of the celebrated anatomist, Mr. Brooks, that the space I have marked out is immediately over the pyloric end of the stomach; and considering the depth of that organ from the surface, and that it may be overlapped by the liver, it will be at once apparent how necessary it is to make the examination in the way I have pointed out. General manipulation here would not detect it.

Secondly. The liver may have become distended; the extent of the distension may be little or much; tenderness also may be combined with it. These conditions are to be discovered in the same way as tenderness of the pyloric end of the stomach. When, however, much of distension and tenderness of the

liver exist, an amount of uncertainty will be thrown over the examination, as far as the stomach is concerned, but, inasmuch as the treatment will be the same, it is a doubt of no moment.

It is, however, to be remarked in this place, that the ordinary modes of manipulation and percussion may be employed for an examination of the liver, in addition, or by themselves; and it should also be stated, on the authority of Dr. Philip, (others could be added,) that it is considered, that when the liver is in a healthy state, free from distension, it does not descend below the ribs, so that the extent to which it has descended may be taken as the measure of its distension. In proof of the correctness of this statement, when not distended, both sides of the epigastric region give the same indications upon examination, made as I have described, as may be seen when examining this region in a perfectly healthy individual. I would also add, as the result of my own experience, that I have seen it distended greatly below the ribs, and under treatment, recede to the normal boundaries.

Thirdly. The duodenum may have become distended, and evince more or less tenderness on pressure. This will also vary; indeed, more frequently the distension, according to my observation, exists without tenderness. The best mode of examining this organ will be in the erect position also, the parts being lightly covered, and the fingers applied at right angles over the organ, and in different parts of its perpendicular course. Where doubt exists as to any distension, examining the corresponding parts on the other side of the mesial line, will at once enable us to decide. Indeed it is very remarkable, the difference which is manifested on examining the duodenum in a state of distension, and the corresponding part of the other side of the body; and when we consider the perpendicular course of the bowel, and how easily any distension of it can be ascertained, we feel inclined to point to it as an illustration of the wisdom and goodness of God, at any rate as affording a means of diagnosis to the medical man, by considering the value of its indications when in a state of distension.

I have thus endeavoured to describe a mode of examination, peculiar in some respects, by which a morbid condition of the epigastric region may be ascertained. To this audience I need not remark, how essential to health is a normal condition of one and all these parts, and I would now take a cursory glance at some of the more obvious exciting causes of an unhealthy condition of this region. If, with reference to the lungs, our care cannot augment the quantity of air inspired, so as to produce disease, but is, or ought to be so employed, that what they themselves excrete, should be, by ventilation, removed at once from within our reach; not so with regard to the stomach. With this organ, the bulk of mankind but slowly learn, even from dear-bought experience, the danger they are liable to whilst supplying the wants of the system. To say nothing of the pernicious practices of the glutton and the wine-bibber, much ignorance and thoughtlessness prevails upon the subject. The knowledge of the art of cookery, for its legitimate ends, needs to be more widely diffused, whilst

numbers in the lower ranks of life not only need this knowledge, but the means to procure more suitable articles for sustenance themselves.

It would appear that the power we have over what should enter the stomach is unlimited, and therefore requires to be rigidly controlled. So that until the knowledge, by means of which we are to regulate the quantity and quality of our food, together with the frequency of our meals, coupled with a disposition to seek enjoyment in the right using of this knowledge, be the portion of each individual, we shall be continually erring, and frequently the sufferers from disorder which might have been prevented. Hence, then, as the chief exciting causes of disease of the organs in the epigastric region, I must mention errors in diet, as to quantity, quality, and frequency, and the abuse of fermented liquors. You easily see how a disturbed stomach influences the function of the liver, retards the flow of bile, and consequently, the passage of the food become chyme through the first bowel. Let this common error be supposed to have been commenced at the period of weaning, and only occasionally repeated through childhood, imagine it then more frequently repeated after puberty, and still more frequently after manhood, and we shall be at no loss to understand how thickening of the lower end of the stomach, with tenderness on pressure, a distended liver, and an enlarged duodenum have been produced.

The second exciting cause of disorder in one or more of these parts which I would mention, is to be found in the character of our climate. Temperate it is, it is true; but, upon the whole, offering us rather too much of a good thing; for, though "variety is charming," it really is so only as an additional exemplification of wisdom and power. The power of adaptation which there is in the human organism not only exceeds that degree of it which is possessed by the higher classes of organized beings, but exceeds probably what we have ever considered it to be under favourable circumstances. But, great as it is, it seems incapable of bearing us harmless through the frequent, sudden, and great changes of temperature which occur in this country. The effect of change of temperature upon the liver, (for I am inclined to think that it is this organ which is directly influenced by temperature, the stomach, probably, indirectly, from the effects of low temperature upon the skin,) may be illustrated by considering the disease which characterizes our hot weather,—viz., English cholera. In this disease every symptom is an effect, directly or indirectly, of the state of the liver, and just in proportion as the means employed are remedies for the disordered liver, do the symptoms disappear. Taking, then, English cholera as an illustration of the effect of change of temperature, accompanied, probably, with as great changes in the electric condition of the atmosphere, upon the function of the liver, I ask for a less effect from a less degree of temperature. Now, when an influence like temperature, a certain degree of which is essential to life, accompanied by as great changes in the electrical condition, varies so much as to be present at one time in such a degree as to exert only its essentially needed influence as one

of the stimuli of life, and at another time, in such a degree as to produce a distressing malady, can we not see in the varying temperature of our climate, the prolific source of deranged function of the liver and its consequences.

The last cause of disease which I shall mention belongs to the class of predisposing, and is to be found in some anormal peculiarity of structure of probably the whole organism; but on this I shall not dwell, except to remark that it is considered by a high authority, that one of the most frequently hereditary morbid conditions, is a distended liver.

Having described the physical examination by which disorder of one or more parts in the epigastric region may be recognized, and alluded to the exciting causes in a general manner, I would say a word or two on the order in which disease is manifested. In the case of hereditary distension of the liver, the first step originates with functional derangement of that organ, involving secondarily the duodenum, and, perhaps, lastly, the stomach, to some extent. In most cases, however, the stomach is the first organ to suffer, then the liver, and lastly, the duodenum. I have before remarked how easy it is to believe the fact of an offended stomach affecting at once the function of the liver, even if it be difficult to understand the mode, as expressed by the term sympathy; still, if we look upon the stomach as having received into its cavity that which it is wholly unable to assimilate, and witness the violent retching which may be necessary to remove it, and, reflecting on the explanation given by this action,—viz., a high degree of irritation of the stomach, which is conveyed by sympathy to the abdominal muscles, inducing in them violent contraction, and so retching, we can get some idea of the meaning intended to be conveyed by the use of that term. Now, a degree of irritation of the vessels of the stomach, which produces vomiting, produces also a perturbed state of the function of the liver, and a less degree of irritation, will affect the liver in a similar manner, but in a less degree, though vomiting be not excited. It is a succession of these actions, which at last ends in a thickened condition of the tissues of the stomach, accompanied or not by tenderness on pressure, according as it has been rapidly or slowly produced. In common terms, we have now established a condition of the stomach, which is below par, a necessary consequence of which is a less amount of healthy stimulus for the liver, which, be it remembered, has, in every step of the stomach affection, been at one time too much, at another, too little, excited, so that we have established at the same time the state of distended liver. Perhaps it is not right wholly to exempt the duodenum from being concerned with the stomach, to a slight extent, in causing the derangement of the liver, but, practically, I think there will be no harm in the plan I have adopted, remarking, that when the duodenum becomes the cause of disturbance in the functions of the liver and stomach, it does so because it has not been aided by the liver to the healthy extent, so that it might pass on its contents, for a substance which has passed the pylorus has done what mischief it had

power to do, ere it reaches the duodenum. The distension of the duodenum then follows the diminished function of the liver, and in this way:—The natural stimulus to the duodenum to pass on its contents is chyme and bile, but in the state in which the liver is, the flow of bile is ineffectually solicited; for whilst chyme and bile excite the duodenum, chyme alone excites the common bile duct, but now in vain. As useless is it towards eliciting a healthy discharge of bile, as would be horseradish to excite saliva in the mouth of a patient suffering under fever.

Having thus noticed the order in which these parts become deranged, I would observe that in practice we are to look only for degrees of this affection.

It may be proper now just to mention a few of the symptoms which will characterize an individual in whom these processes may be going on. Take, then, unequal and slow growth as an effect of the *hereditary* abnormal condition of the parts in the epigastric region to a certain extent, as deranged in common with the whole; and as evidence that the parts in this region are disordered, there being no hereditary taint, look at convulsions in a child, not arising from any idiopathic affection of the nervous system, nor from teething, but from some indigestible article taken as food. Has this indigestible substance made frequent attempts to pass the pylorus, but in vain? and is this resistance which has been opposed to its passing to end there? In what portion of the digestive apparatus would you look for the origin of the disturbance in the nervous system you are witnessing, if not here? This condition, I would again observe, is frequently represented by the sick headache of youth and adult age; and what more distressing liability for any man. For its importance, as a symptom to be remedied, witness the complexion and the paleness of the countenance, with its languid eye; see the wearisomeness of any effort made to discharge a duty which cannot be delayed; mark the disinclination to hear, to speak, to move; see how thoroughly an individual is unmanned by a bilious headache, and judge whether it be a matter of importance to be aware of the precise condition of the deranged parts of that organism, and of the means by which it is to be remedied. For this information I need not say the profession, or rather our country, is indebted to the indefatigable Dr. Wilson Philip, and it is because I fear his opinions are not so extensively known as their importance, in my judgment, requires, that I have presumed to make them the subject of this paper. It is this condition of the stomach, liver, and duodenum, which constitutes a bilious condition; and, I believe, until it be recognized as such, and the patient treated until he be cured, so long will a bilious headache be left to be remedied by the suggestions of empiricism, and be the prey of the charlatan.

There are other constitutional maladies, the course of which is intimately connected with derangement in the epigastric region, as rheumatism, gout, &c. Cases of fever in children, perhaps, preceded by, or at any time accompanied by, relaxed bowels, the evacuations being liquid, pale, offensive, which you attempt to restore to convalescence successfully, only in proportion as you

correct the state of the hepatic function. In the specific diseases of children, the course they will pursue, and the presence of unusually grave symptoms, are often materially dependent on the condition of the digestive organs, as represented by the state of the epigastric region. Again, this condition, more frequently than any other, lies at the foundation of certain states of general disorder, in which case it is often stated that there exists no local condition capable of giving rise to this undefined general ailment, a case which, in the opinion of the writer, is more rare than is generally supposed. On this part of the subject I would remark of this morbid condition, that it is frequently the cause why tonic remedies cannot be borne by the system, and yet the system is loudly calling for an invigorating treatment. Lastly, in my own experience, I have found this condition of the epigastric region more frequently than any disorder of any other organ or organs, the cause of common febrile disturbance as differing from continued fever. It should not be omitted to be mentioned, and I mention it lastly, because of its importance, that, by Dr. Philip, this condition, especially the state of the liver, is regarded as the cause of consumption in the vast majority of cases which occur in this country, and he goes so far as to state, that by recognizing this condition, and remedying it, consumption may be *prevented*.

His view of the mode in which it thus acts, I understand to be as follows:—This morbid condition which I have been attempting to describe, having been in existence a long time, acts as a fret of nerve upon the brain and spinal marrow, debilitating them in their functions, from which organs you are aware, he derives the true nervous power, on the presence of which depends the healthy action of every organ in the system, as Doctor Philip contends, his experiments demonstrate. This state of the nervous system—debility of the brain and spinal marrow—constitutes the second stage in the changes of the system, which is at last to end in embarrassment of the function of the lungs, where the tendency exists, then, to the deposition of tubercles. Now, the effect of this debilitated condition of the nervous system, falls, sometimes on one organ, sometimes on others. In the case of consumption, the lungs suffer, engorgement follows, and that action to which they are most prone, takes place. This is the third stage in the order of events, and is manifested by the ordinary symptoms of tubercular degeneration. Dr. Philip states, that when he has seen a patient in whom the symptoms of mischief in the chest have existed only a fortnight, he has been enabled to arrest the development of tubercles. In confirmation of the correctness of these principles, he states, that he has treated cases in many families, in which hitherto they had been dying-off fast of consumption, and that by acting on these principles the ravages of that malady have been arrested. My own experience, even if in confirmation of them, must necessarily be very limited; I can point to one family where four out of seven had fallen a sacrifice, and can attribute to nothing else than the partial adoption of these principles, the at present healthy condition

of the remaining three. One other case is that of a female ill with continued fever, in whom this morbid state of the organs in the epigastric region existed to a great degree. It was recognized and treated accordingly. She recovered, and has continued in the enjoyment of health ever since. Her family subsequently left the town for Northamptonshire. A few months since the father called on me, telling me that he had been spitting blood, and that his case was considered one of consumption. At the time I was in attendance on the daughter for fever, he was ailing frequently with headache, costive bowels, want of energy, and sallow complexion. But to have prescribed for a man who did not consider himself to be needing any advice would have been an useless attempt. The stage where consumption might have been prevented, was, unconsciously to him and myself too, allowed to pass away unimproved, and an effect followed, which science could have prevented, but cannot cure. He told me also, that he had buried one daughter who had died of consumption, and that another was doomed. Happily, the one which I attended for fever, was in the enjoyment of health. To me, this is valuable evidence in confirmation of the soundness of principles, the object of which is not to cure consumption, but to prevent its coming into existence. And when can we think of a disease which is carrying off its scores of thousands of victims in England alone every year, with any satisfaction, if it be not when considering any reasonable mode by which it can be prevented. I would only add, surely these principles, which embrace such an object, deserve the calm judgment of an enlightened and benovolent profession, but for the grounds on which Dr. Philip bases his doctrines, I must refer you to his works.

This brief and imperfect description of certain morbid derangements of the organs in the epigastric region, you will consider should have with it a glance at the means to be used for its relief. As to the diet which will be proper for a patient under treatment, I need say nothing to this audience. Cases in which the mucous membrane of the stomach and duodenum is in a state of subacute or chronic inflammation, not only require a diet easy to be assimilated, but as little in the way of food as the patient can do with. It should also be duly considered, that as the mucous membrane is the first to become affected, so it must be the first to be remedied in the treatment of these cases; for in proportion as this morbid condition of the stomach is corrected, is the way cleared for a successful result from remedies designed to relieve the liver, and where the exciting causes have been such as to involve not only the stomach but also the duodenum, must the relief of that organ proceed with the relief of the inflamed condition of the pyloric end of the stomach. When there is tenderness on pressure, cupping or leeches on the part specified for examining the organs, and repeated once in four days or a week, according to the severity of the case, will be proper. Calomel is to be given on alternate nights, commencing with a grain, made into a pill with extract of liquorice, and to be followed by

some suitable laxative in the morning. When a grain of calomel with the morning laxative is insufficient to act two or three times on the bowels in the forenoon, a grain and a half may be given, and it may be gradually increased to any quantity, so long as it is carried off by the laxative in the morning, and the gums remain unaffected—an object to be, except in certain cases, scrupulously avoided. With this treatment may be given some nitrate of potash, or Mindererus' spirit, with or without ipecacuanha. In females, sometimes calomel cannot be borne, in which case, blue pill, in doses of from three to five grains can be used. When the tenderness has been removed, the exhibition of a tonic dose of calomel or blue pill is to be given every seven or eight hours. This tonic dose consists of a grain of calomel, or ten grains of blue pill, made into twenty pills, with extract of liquorice and ginger, or with any other medicine which accompanying symptoms may require. With this change in the additional use of means, may be given some stomachic tincture twice in a day. Occasionally, counter-irritation may be required; but in what cases, and for any fuller information which may be wished, I beg to refer to the writings of Dr. Philip.

There are certain cases in which this treatment is found wholly inadmissible, as that peculiar idiosyncrasy of constitution, which at once, from a single dose of any mercurial preparation, is thoroughly salivated. Another case is that of an individual in whom the mucous membrane of the alimentary canal is so irritated by a mercurial preparation, that to persevere would be to make the patient worse instead of better. Again, the disposition to profuse uterine discharge which afflicts many females, often proves a source of much embarrassment to the practitioner. And sometimes the state of the nervous system is such, and the circumstances are altogether so unfavourable for the endurance and perseverance necessary to restore healthy action, and to maintain it for a certain time, in an organ which has been for a long time out of health, that to attempt the cure would only be to encounter disappointment.

REMARKS, HISTORICAL AND PRACTICAL, ON DISEASES OF INFANCY.

By E. COPEMAN, M.D., Norwich.

There are few subjects, perhaps, which have engaged more of the attention of medical practitioners within the last few years, than the diseases of children; nor is there, probably, any branch of medical science which has received greater advancement from the labours of those devoted to its elucidation. For a long time neglected, and therefore very imperfectly understood, the diseases of children were treated, (if treated at all save by mothers and nurses,) without the slightest regard to anything like system or practical discrimination. If a physician deigned to notice them at all, his treatment consisted in the merest empiricism, and it appeared as if it were hardly expected that any good could result in such cases from the interference

of a professor of the medical art. In the early part of the eighteenth century, however, some little progress was made in this department, and in 1715, a work entitled "*De Morbis acutis Infantum*" was published by Dr. Walter Harris, a learned physician in great repute at the Court of William and Mary, and whose writings bespeak him to have possessed a highly religious and exemplary character. He was an intimate friend of the great Sydenham, by whose advice it was, he informs us, that he made public his method of treating infantile disorders. His descriptions of disease are by no means clear, nor does he treat much of symptoms; his principal object is to direct attention to a more successful method of treatment than had hitherto prevailed. Dr. Harris' plan is indeed sufficiently simple, and if as universally applicable as he believed it to be, it would save the physician an immensity of difficulty in diagnosis, and remove almost all doubt about the choice of remedies. He says, "As the constitution of young persons is very humid, I do not hesitate to pronounce that all their diseases are of the same kind, and produced by one and the same cause; and that according as different parts of the body, whether upper or lower, are affected with this or that disease,—according, for instance, as the stomach, intestines, lungs, head and nerves are chiefly affected, different names are allotted to the same disease." Thus, according to his theory, all the diseases of children arise from one and the same cause, this being the natural humidity, or fluids of the body, degenerating into an acid. "*Porro symptomata infantum singula acido, ut parenti legitimo, ortum suum debent.*" From these simple premises, he deduces an equally simple indication of treatment; namely, to neutralize the predominating acidity by testaceous powders in large doses, and to purge them off at intervals. The powders were to be given two or three times a day in some aromatic water, and every two or three days, an aperient of rhubarb alone, or mixed with cream of tartar, to remove the contents of the bowels. Several cases are narrated in which the effect of this treatment was remarkably beneficial in various acute diseases of infancy; and this comprises nearly the whole of what is to be learned from his book upon the subject of infantile diseases. In convulsions, Dr. Harris recommends bleeding, under certain circumstances, but only in the intervals between the fits, and not during the fit. On the subject of bleeding in general, he offers some sage remarks deserving of being quoted. "As regards venesection in children, although a marked transference of the febrile matter into the lungs, and *convulsive coughs*, sometimes require it in the smallest infants; yet it is very manifest that it is not a remedy adapted to their nature, nor better suited to this most tender age than for decrepid old people. I do not therefore think it at all necessary to require its aid in any affection of infancy, except in convulsive coughs, or where a troublesome cough accompanies a fever of sudden origin, &c." Rhubarb he extols as without exception the best purgative for children, and considers aloes injurious; also Cethiop's mineral as the best mercurial "*quia qualicunque quantitate, et quotiescumque exhibita salivationem non solet excitare.*" Dr. Harris thus sums up his remarks upon the treatment of acute diseases of children, and I transcribe his

own words, even at the risk of being considered prodigal of quotations, because the conclusion arrived at from his experience, his desire for improvement in practice, and his dependence on Providence for the success of means judiciously employed, can scarcely be more briefly or more forcibly expressed. "I am fully persuaded, after a long life and much experience, that the more simple methods of cure, unlike the elegant technicalities of certain learned men, are generally more grateful to the stomach, more conducive to the restoration of health, and are more frequently accompanied with the divine blessing, than a pompous farrago of medicines, however much a manifold authority, new or old, may militate against this opinion or contradict the simple truth." The method of prescribing, at the period in which Dr. Harris practised, and before his time, was so contrary to the simple plan he advised, and consisted of such an incongruous mixture of multifarious ingredients, that it was not likely he should live to see old prejudices surmounted, and his plan generally followed; indeed, for many years after his death, the art of prescribing remained complicated and indefinite, and it was left for the present generation to separate the good from the bad,—to choose the former and reject the latter,—to profit by the advanced state of botanical and chemical knowledge,—and thereby to contribute materially to the alleviation of the various ills of mortality.

(To be continued.)

CASE OF POISONING BY ARSENIC,

PRESENTING SOME PECULIARITIES.

By M. M. DE BARTOLOME, M.D., Sheffield.

(Read before the Sheffield Medical Society, Oct. 2nd, 1848.)

The destruction of human life by the agency of poison has of late years been most lamentably on the increase, and although the improved and daily improving state of chemical science fortunately enables us to ascertain with ease and certainty, (at least in the case of mineral poisons,) the precise poison employed, yet cases are now and then met with presenting certain anomalies, either in the *post-mortem* appearances, or in the results of the analysis by which we endeavour to detect the poisoning agent employed. Conceiving that it is the duty of every medical man to lay any such cases which may fall within the scope of his observation before the profession generally, I am induced to bring before this Society the following case, and in doing so, I shall endeavour to call your attention to those points of resemblance to, or deviation from, the usual routine of similar cases:—

The subject of the melancholy investigation which I am about detailing, was Mary S., a scissor-burnisher. It appears from the evidence at the inquest, that an improper intimacy had for some time existed between her and an apprentice, who was frequently employed in the same room with her, the result of which was her becoming pregnant; and it likewise appears that she had frequently expressed her determination never to become a mother, although both the lad by whom she

was "*enceinte*," and another man with whom she "kept company," had often expressed a willingness to marry her.

On Wednesday, August 16th, 1848, she left her home about 7 p.m., and returned about 9 p.m., during which absence it is supposed she procured the poison, either by buying it herself, with a view to self-destruction, or by having it from some one with the intention of inducing abortion. On this point we are completely in the dark, for although the police enquired at more than fifty druggists' shops in the town, not the slightest information could be gathered by them, either to establish the fact of her having bought the poison herself, or tending to criminate others. On her return home she complained of being very ill, and her mother made her some gruel, into which it is presumed the poison was put by herself. On the following day, as she continued very unwell, her mother gave her some Epsom salts, and again on the Friday, her suffering still continuing, her mother gave her some castor oil; but no one having any suspicions of the real state of matters, no medical man was sent for until about ten minutes before her death, which occurred on Friday, August 18th, at 8 p.m., although vomiting and purging had existed, almost without intermission, for upwards of twenty-four hours. Mr. Martin having been sent for, and being from home at the time, Mr. Newton, his assistant, saw her, as I have stated, about ten minutes before her death, which actually took place while he was still in the house.

On Sunday, August 20th, 1848, at 9 a.m., thirty-six hours after death, the body was inspected by Mr. Martin and myself, assisted by Mr. Newton. The body externally presented no marks of violence, but it was much ecchymosed from gravitation. About midway between the pubis and umbilicus a tumour was felt, like a truncated cone, which, on removing the abdominal parietes, proved to be the uterus, evidently in an impregnated state. The head externally presented nothing abnormal. On the surface of the brain there was a good deal of venous congestion, and its substance presented a much greater number of bloody points than natural. The ventricles contained about half an ounce of serum each. The cortical matter of the cerebellum was more injected than that of the cerebrum; the medullary less so. *Thorax*:—The right lung was perfectly healthy and crepitated freely; the pleura on the same side was healthy; the left lung was likewise healthy, and crepitated freely, but the left pleura was adherent all over its surface. The heart was rather larger than natural, particularly the right side; otherwise apparently healthy; on cutting into it, however, its substance was found very flabby, and its cavities filled with coagula—particularly those of the right side. The valves were all perfectly healthy. *Abdomen*:—The peritoneal coat covering the fundus uteri was more injected than natural, and in some places ecchymosed, giving the viscus a mottled appearance. The fundus uteri, at its broadest part, was about seven inches in diameter, and from the fundus to the os uteri the distance was nine inches. On cutting through the fundus uteri an ecchymosed

patch, about three inches by one and-a-half inch, was seen between the membranes on the middle of the anterior surface, and another similar patch lower down. The placenta extended across the cervix uteri, and was partially separated. The membranes enclosed a fœtus, eleven inches long, and apparently from five to six months old. The stomach and bowels were distended with gas; the peritoneal coat over the large curvature of the stomach, and on the right side, presented many congested patches of various sizes, from half an inch to an inch in diameter. These patches nearly coalesced, so as to give the stomach the appearance of general external congestion over an extent of about four inches by two. The large intestines were healthy externally, but the small were rather more injected than natural. The liver was very pale, and rather mottled; its edges attenuated and condensed. The right kidney was gorged with blood; the left not so much congested. The stomach and its contents, as well as the contents of the intestine, were removed for examination. The intestines internally were, generally speaking, healthy, but rather exsanguine, except here and there a slight ecchymosed patch of no importance. In almost every portion of the intestines a yellow gritty matter was found in considerable quantity, and perfectly detached. *Stomach internally*:—The mucous membrane presented several highly congested patches, some of which corresponded with the congestion observed on the peritoneal coat, whilst others were independent of it, but all of them appeared upon the pyloric end of the stomach. In no part of its surface was the mucous membrane ulcerated. Along the lesser curvature of the stomach a yellow gritty matter similar to that seen in the intestines was found in considerable quantity. So far as we could judge by the eye there were at least twenty grains of this substance altogether. It presented the colour and general appearance of sulphuret of arsenic, and was of an homogeneous colour.

This substance, on being analysed by us, proved to be the sulphuret of arsenic. On its being simply heated in a tube, with charcoal and carbonate of soda deprived of its water of crystallization, a metallic ring was produced, presenting all the characters of metallic arsenic. Another portion heated with the same flux, in a tube open at both ends, sublimated into arsenious acid, which, on being dissolved in boiling distilled water, gave with the liquid tests the most conclusive evidence of the presence of arsenic. Another portion of this yellow matter was boiled in distilled water, filtered, and the tests applied to it, but without any satisfactory result, even after the addition of caustic ammonia. A portion of the liquid contents of the stomach and intestines was then filtered and the tests applied as before, without detecting arsenic. Another portion was boiled in diluted muriatic acid, and properly prepared animal charcoal, and then filtered. This was divided into two portions—one was simply tested as usual by all the liquid tests, and to the other caustic ammonia was first added and then tested; but in neither case was the least trace of arsenic found.

Some of the charcoal left upon the filter was next dried and put into a tube with desiccated carbonate of soda, and on the application of heat the metallic ring and likewise a ring of arsenious acid were produced; and on the latter being boiled in distilled water, and tested in the usual way, the most satisfactory evidence of the presence of arsenic was obtained. A small quantity of the same charcoal was then treated with caustic ammonia, and on being tested produced the same results.

I may here mention, that the tests used in the different processes detailed above were—Ammonio-Nitrate of Silver; Ammonio-Sulphate of Copper; Sulphuretted Hydrogen; Lime Water; Bichromate of Potass.

From a careful consideration of the foregoing facts I am decidedly of opinion that the form of arsenic taken was the sulphuret, at all events that it was not arsenious acid; and to this conclusion I am led, both by the results of the chemical analysis carefully performed, and by the *post-mortem* appearances. I am further inclined to think that it was a native and not an artificial sulphuret, because of the length of time the patient lived after taking it. Native sulphuret of arsenic is nearly, if not quite, insoluble in water, whilst the artificial sulphuret generally contains as we shall presently see, a considerable portion of arsenious acid.

The results of the chemical analysis clearly proved that the liquid contents of the stomach and intestines contained no arsenic in a soluble form, but merely held in mechanical suspension; and hence we find that although the solid matter left upon the filter gave both by reduction and by the liquid tests after solution in ammonia, convincing proofs of the presence of arsenic, not the slightest trace of this metal could be detected in the filtered fluid. Again, the gritty yellow matter so abundantly found in the stomach and intestines, was of an homogeneous yellow colour; and we can scarcely imagine a state of the digestive organs so totally depraved as to produce a quantity of sulphuretted hydrogen sufficient to change the whole of the arsenious acid taken, into the sulphuret of arsenic, in the short space of two days.

Christison, speaking on this subject, says, "Sulphuret of arsenic sometimes exists in small quantity in the stomach although the poison was given in the form of oxide." And in the account of a case examined by Professor Traill of Edinburgh, five months after interment, we are told, "the contents of the stomach consisted of a considerable quantity of yellow sandy matter, of the consistence of paste. The contents and adhering crusts were found to consist chiefly of oxide of arsenic partially converted into sulphuret. If five months were not sufficient time to convert the whole of the arsenious acid into sulphuret, and the crusts were only partially so converted, we cannot, I think, suppose that two days could by any possibility be sufficient to perfectly effect the change and leave no vestige of the original arsenious acid."

The appearances found after death seem, in my opinion, to lead to the same conclusion,—viz., that the metal was not taken in the form of oxide, for they

were by no means such as are generally found in cases of poisoning by arsenious acid; and indeed, some of them are diametrically opposed to those described by some authors; I shall, therefore, claim your indulgence while I briefly notice some of the most remarkable, as nearly as possible, in the order in which we observed them.

The peritoneal covering of the stomach, as already stated, was found considerably congested—an appearance seldom found according to Christison, for he says, "It is singular that, however severe the inflammation of the inner membrane of the stomach may be, inflammatory redness of the peritoneal coat is seldom found; yet inflammatory vascularity does occur sometimes on the peritoneal coat."

The mucous membrane has been represented by various authors as being in such cases soft, brittle, and easily separable. In the instance at present under consideration, the contrary was the case, for this membrane was quite as firm as usual—a state which certainly tends to strengthen the supposition that the poison taken was not arsenious acid; for it is, I think, very improbable that any arsenious acid could have remained for two days adhering to the mucous coat of the stomach without causing a more violent degree of inflammation than was observed in this case, and without inducing the more or less extensive destruction of the mucous membrane.

Speaking of the effects of arsenious acid upon the intestines, Christison says, "It is a curious fact, that the rectum is sometimes much inflamed, though the colon, and more particularly the small intestines, are not." Dr. Male and Dr. Baillie have recorded cases in which the rectum was redder than the stomach itself, and the anus ulcerated, and even in a state of gangrene. Bachmann and others have stated that they have found the external parts of generation much congested, and in females even in a state of gangrene. In the case of Mary S., the contrary was observed. The small intestines alone were more injected than natural, whilst the large intestines, the anus, and the external parts of generation, were perfectly healthy.

Pyl relates a case in which the inside of the uterus and Fallopian tubes was inflamed, and this certainly agrees with the condition in which those parts were found in the present case.

The lining membrane of the heart is represented by some authors as being unusually red, and Brodie and Wildberg assert that the blood of animals killed by arsenic is commonly fluid, whilst, on the other hand, Wepfer, Sproegel, and Jaeger, state that it is black and semigelatinous. If our case is to decide between these authors, we must pronounce them all right and all wrong, because we found the blood contained within the heart coagulated, but rather florid than otherwise—certainly not black.

It may be urged by those gentlemen who may differ from me in opinion as to the form of arsenic taken in this instance, that the sulphurets of arsenic are not so easily procured as the arsenious acid itself, nor so likely to be known as poisons by the vulgar; but this objection loses much of its force, when we remember

that in the celebrated Bristol case, published by Dr. Symonds, it was proved at the trial, "that the poison used was artificial orpiment."

Dr. Duncan met with an instance of an attempt to poison by mixing King's yellow with tea. Another case is related by Christison, in which King's yellow was intentionally taken in Edinburgh, and proved fatal in thirty-six hours; and another which occurred at Glasgow, in 1822, where a woman was tried for poisoning her child with the same substance.

In the Bristol case death took place within a very few hours, and on a sample of the poison obtained at the same druggist's shop where the fatal dose had been bought, being analysed, it was found to contain no less than 79.100 of arsenious acid. This was probably the case in the instance given by Christison, as occurring in Edinburgh, in which death took place in thirty-six hours.

In conclusion, I will merely mention that Hahnemann, who is generally considered as having over-estimated the solubility of the sulphurets of arsenic, states that native orpiment is soluble in 5,000 parts of boiling water, and the artificial in 600, a difference in solubility which could only be accounted for by the fact already named, that the artificial orpiment contains a large proportion of arsenious acid, which is soluble in 16 parts of boiling, or in 100 parts of cold, water. It is now, however, pretty generally supposed, that Hahnemann was mistaken, and that the sulphuret is not dissolved, but decomposed by the water, which, by giving it its oxygen, converts it into arsenious acid, the hydrogen and the sulphur set free by this double decomposition, forming sulphuretted hydrogen, which is then evolved.

I had almost forgotten to call your attention to the enormous quantity of the poison which this unfortunate girl must have taken, since, although vomiting and purging had continued almost without intermission for upwards of twenty-four hours before death, so large a quantity as twenty grains was nevertheless found in the alimentary canal.

ON THE MINUTE ANATOMY OF THE AIR-CELLS.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

It is at present a disputed point in microscopic anatomy, whether there exists any epithelium on the internal free surface of the air-cells of the lungs. In his interesting paper "On the Minute Structure of the Lungs,"* Mr. Rainey has confirmed the opinion that the ciliated epithelium does not extend farther than the point at which the bronchial tubes terminate abruptly in the intercellular passages, "after which the passages conducting the air continue in the same direction as the bronchial tubes, of which they are the continuation, but without having any perceptible membranous

* Medico-Chirurgical Trans., Vol. xxviii., p. 581. 1845.

lining, their parietes being formed merely by the air-cells between which they pass, and by which they are surrounded." Mr. Rainey subsequently remarks that "those parts in which the aeration of the blood more particularly takes place, are lined only by a very thin fibrous membrane," and explains away Mr. Addison's observation of round nucleated epithelial scales in the air-cells, by assuming that that physiologist mistook the remains of nucleated cells in the walls of the capillaries for epithelial scales.

Having taken some pains to investigate the minute anatomy of the lung, I believe the following to be a correct statement of the facts:—

The columnar ciliated epithelium terminates with the termination of the bronchial tubes, precisely as Mr. Rainey so clearly describes, but beyond this the basement membrane of the intercellular passages and of the air-cells is covered with a delicate transparent pavement epithelium, the individual scales of which are irregular in shape and size, and present a single nucleus in each, not, I believe, "from one to fifteen or more nuclei" in a single scale, as Mr. Addison states.

The proof that these scales are not situated within the capillaries, is furnished by the circumstance that a portion of them may be displaced from the surface of the object without injury to the tissue.

In outline, as in size, the scales vary greatly, but are never exactly either circular or oval. They always present angles at some part of their circumference. The pentagonal is a common variety.

Non ciliated pavement epithelium exists in the air-bladder of fishes, in the lung-sac of reptiles, and in the air-cells of the lungs of birds and mammals. I have drawings and dimensions of it in each of these organs, but as I wish to view the objects with polarized light, which at present I have not been able to do, I defer a more particular description to a future opportunity.

The precise mode of termination of the circular muscles of the bronchial tubes has not hitherto been described. These fibres, being external to the longitudinal fibres of yellow elastic tissue, cease where the longitudinal fibres divaricate to bound the air-cells, into the walls of which they enter in sweeping curves. In the bronchial tube the longitudinal fibres are packed side by side, and pursue a straight course; where the tube ends in the intercellular passage, the longitudinal fibres immediately spread out, separating from each other to form the frame-work and support of the membrane which constitutes the wall of the intercellular passage and air-cells. The bronchial muscles ceasing with a defined edge at the end of the bronchial tubes, are prevented by the spreading out of the longitudinal fibres around the intercellular passages and air-cells, from ever acting like a sphincter muscle at this point, which, had the elastic fibres been external to the muscular instead of internal, might probably have sometimes taken place, to the great detriment of respiration.

I am, Sir,

Your obedient servant,

C. RADCLYFFE HALL.

Holmes Chapel, Cheshire,

December 6, 1848.

PROVINCIAL Medical & Surgical Journal.

WEDNESDAY, FEBRUARY 7, 1849.

We have on various occasions reported the case of "*Cox v. the Midland Railway Company.*" The action was brought by Professor Sands Cox, of Birmingham, to recover from the Midland Railway Company, the amount of his charge for professional services, rendered at the instance of the Company's servants, in the case of an accident occurring to a passenger on that line. For reports of the original trial before Mr. Justice Maule, and of the subsequent proceedings, we must refer to former numbers of this Journal. We have now to announce the decision at which the Court of Exchequer has arrived in this important case. The law of the land in reference to all such matters is thus laid down by Mr. Baron Parke:—

"The Court was unanimously of opinion that no power to enter into any such contracts as those on which these actions were brought, was incidental to the employment of a guard or superintendent of a railway company. Those servants did not stand in any different position from that occupied by the servants of any other company or partnership, or of any individual. It could never be contended that if a passenger fell from the roof of a coach and suffered a severe injury, the coachman had any implied authority to bind the owners of the coach to pay for any professional aid which he on the instant might think proper to call in for the relief of the passenger. Such a contention could not be maintained in the opinion of the whole Court; for, though it might be that the owners would be benefitted by such contract if they were liable to the passenger for the accident, it would, on the other hand, prejudice them if they were not so liable. A servant, therefore, clearly had no such power of pledging his master, for he received from them only that extent of authority which was necessary for the discharge of the duties required of him under ordinary circumstances. When extraordinary events occurred which required an excess of those ordinary duties, it was the duty of the servant to apply to his employers for further powers, and he could not bind them if he assumed them without such application."

We are, hence, we presume, to infer that a passenger, or any number of passengers, who may be placed in various circumstances of danger, however imminent, from the result of a collision or other railroad accident, are to be left in that situation, if unable of themselves to apply for, or authorize the application for, such surgical assistance as their case may require, until the superintendent or other officer of the Company shall have summoned a Board of Directors to obtain the necessary powers. Any surgeon obeying the summons of the

railway officers to such an accident, and bestowing his services under such authority, must now be understood to render those services gratuitously, with the further certainty also, in the event of his attempting to enforce his just claim for remuneration, of a heavy pecuniary loss in the shape of legal expenses.

It will be remembered that on the original trial, in which the verdict was given in favour of the plaintiff, Mr. Justice Maule, who presided on the occasion, recommended that a notice should be put up by the company, that "no medical assistance would be rendered on this line in case of accident." This suggestion, sarcastically made by the learned judge on that occasion, has, as is observed in an able leading article on the subject in the *Times*, now received the deliberate sanction of a well-considered judgment of one of our superior courts. Such it appears is the law of the land, and our contemporary may well question whether it should remain so one moment longer than the time which may be necessarily devoted to its extirpation.

Such a change in the law as is here intimated, desirable or rather imperatively necessary though it be, will not, however, meet the exigencies of the present case, nor place the gentlemen who compose the Board of Management of the Midland Railway Company, on a reputable footing with the public. We have no acquaintance that we are aware of, with any of these gentlemen. We do not even know their names, but we have no doubt that they are "all honourable men," and we deeply regret that on their public character should rest such a stain as the whole circumstances of the present proceeding cannot but entail. Take for instance the subjoined features in the case, which we extract from the columns of a Birmingham newspaper:—

COX v. THE MIDLAND RAILWAY COMPANY.

To the Editor of Aris's Gazette.

SIR,—As the case may receive some notice in your next paper, I shall be obliged if you will allow me to state that before I brought this action I knew that the Company's servants had employed Mr. Cox, and that Higgins had been induced to compromise his claim for £150 only, on condition that the defendants "should pay the medical and surgical charges." The only defence I heard of was, that Mr. Cox's charges were unreasonable.* At the trial I had abundant evidence to show they were not; and Mr. Humfrey (defendants' counsel,) said he had no complaint to make on that head, but that the defence was, that the Company's servants had no authority to employ Mr. Cox; and, on referring to

their undertaking to pay, I was answered that the Company had not authorized their Counsel to make any such promise.

I am, Sir, your obedient servant,

JOHN SUCKLING.

Cherry Street, Jan. 20, 1849.

* Mr. Cox's charges for amputation, and attendance during the whole of the night, were £21, and £3, 3s. each for two subsequent attendances, a distance of ten miles from Birmingham.

COX v. THE MIDLAND RAILWAY COMPANY.

To the Editor of Aris's Gazette.

SIR,—Assuming that you will notice the decision of the Court in this cause in your paper on Monday next, I think it right, as the attorney of the poor man Higgins, who received £150 from the defendants by way of compromise for the loss of his leg, that the public should be acquainted with the fact that I declined to advise Higgins to settle the action for that sum, unless the surgeons' and innkeeper's bills were paid; and upon the promise of defendants' Counsel that the £150 should be "*exclusive of medical and surgical charges and innkeeper's bill*," which the Company should pay, I was induced to settle upon such terms.

I am, Sir,

Your obedient servant,

GEORGE CHILWELL.

Birmingham, Jan. 20, 1849.

Now, we beg to ask,—first, whether, in conformity with the terms of the compromise, the Company have paid the innkeeper's bill; secondly, whether they, in violation of those terms, have thrown that bill on the poor disabled sufferer Higgins, leaving him the chances of an expensive legal process for compelling them to abide by their compromise in this respect; and thirdly, if they have so paid the innkeeper's bill, on what principle do they refuse to defray the charges for medical and surgical attendance, seeing these were also included in the terms of the same compromise.

They may possibly avail themselves, and legally, of the decision which they have just obtained in the higher courts; but if they do not discharge the surgical expenses, and moreover, reimburse Professor Cox to the full amount for the expenses to which he has been put, by the legal processes rendered necessary to establish the principle, for which we presume they can alone have been contending, their moral code of action will be, to our apprehension, of a very peculiar nature indeed, and such as we should ill like to trust to, in any dealings, public or private, with our fellow-men.

By a notice which appears in our advertising columns, our readers will find that the General Meeting of the Poor-Law Medical Officers is now

appointed to be held on Monday, the 19th inst. The meeting is one of no ordinary importance, as the present seems to be the time when a strong appeal to Parliament, well-backed by the profession at large, may be expected to lead to some amelioration of the system at present pursued.

Reviews.

The London and Provincial Medical Directory. 1849. pp. 532.

The principal alterations which we observe in this most useful work are the omission of the Medical Diary and the insertion of a Street List of the Medical Practitioners of London and its suburbs. The work is, moreover, evidently more complete than its predecessors, as we judge from the increase in the number of its pages, amounting to nearly one fourth more than those of the Directory for 1848, which, through the arrangements of the publisher, are yet comprised within a smaller bulk, so as not to interfere with it in any respect as convenient for reference. Our readers may rest assured that they will not only meet with much information on various matters connected with the profession and its members, but that until a legal and compulsory system of registration shall be adopted, no more efficient method of marking the genuine qualified practitioners could well be devised. Imperfections and errors may indeed occasionally be detected, and in a work of this kind it is most important that they should be as few as possible, but in many of the instances which might be referred to they are rather owing to the neglect of the instructions sent in the circulars for information, and can scarcely be attributed with justice to the Editor, who we firmly believe has exercised as much care as the nature of the undertaking would admit of.

Medical Portraits.

We have received two more of these interesting memorials of eminent members of the profession, executed by Mr. Macguire, in the same style of excellence as those already published. The portraits of Dr. Forbes and Dr. George Budd will both prove acceptable to the subscribers to the work, but that of Dr. Forbes will be especially so to the members of the Provincial Association, to so many of whom he is well known, and by all highly appreciated. The likeness has every appearance of being a faithful one, and it is with some shade of melancholy that we say so, as in contemplating the deeply intellectual features of our esteemed friend, we cannot but feel that the two or three years which have intervened since we last saw him, have not passed without leaving their traces on his countenance.

Proceedings of Societies.

BIRMINGHAM PATHOLOGICAL SOCIETY.

November 2nd, 1848.

W. C. FREER, Esq., in the chair.

PERFORATING ULCER OF THE STOMACH.

The preparation had been given to Dr. Russell by Mr. Simons, who attended the case, and furnished the following report:—

A woman, aged 24, single, chlorotic, with deficient and irregular menstruation; she always complained of pain in the region of her stomach after food, and thought herself troubled with worms; was always in the habit of taking medicine. October 27th. She got up in her usual health; whilst rubbing the fender was seized with sudden violent pain in the region of the stomach; this was about 8 a.m. She said that something had given way inside her. The pain increased. Mr. Simons was sent for about 1 p.m. He found her with her body and face cold; a clammy perspiration had broken out over her; pulse excessively feeble; face very pale; nausea, but no vomiting, nor did vomiting occur at all; violent pain extending over the whole abdomen, which was tender, and seemed distended. He ordered fomentations, and prescribed ammonia and opium. A few hours after he found her somewhat easier, but still making great complaint; some re-action had taken place. She was very anxious to have her bowels open; so, fearing what the case was, Mr. Simons only prescribed some rhubarb and carbonate of magnesia, in peppermint water. In one or two hours after, she passed one healthy solid stool, and felt relieved. During the night a woman slept in the same bed with her; this woman awoke at 4 a.m., and found her quiet, as she supposed. She again awoke at 7, and found her dead and cold.

Sectio cadaveris, sixty hours after death. A tolerable amount of fat in the subcutaneous cellular tissue. *Heart and lungs* healthy; coronary vessels loaded with blood. About three quarts of fluid in the cavity of the abdomen; this fluid consisted apparently of what had been swallowed; it did not contain any lymph. *Stomach* about the ordinary size; at the cardiac extremity, in the anterior wall, near the small curvature, was a perforation; exteriorly the aperture almost admitted a lead pencil; the ulcer in the mucous membrane and muscular coats, was the size of the end of one's finger; the coats of the stomach were generally thicker than natural; the mucous membrane around the aperture was firm; no injection of the mucous membrane, nor any cicatrix nor other ulcer. *Intestines* healthy externally. *Liver* rather small, pale; its cut surface unusually smooth; the acini less distinct than natural. The microscope detected a considerable quantity of fat in the cells of this organ. *Uterus* healthy.

Mr. Wickenden remarked that these accidents generally occur in chlorotic girls and young women. He referred, however, to a case in a married woman, in whom death took place eleven hours after symptoms of

perforation came on; the symptoms set in immediately after a walk taken on a full meal. The ulcer was in the posterior wall.

Mr. W. H. Partridge mentioned another case in an old gentleman.

Dr. Fletcher remarked on the sensation of "something having given way in the stomach," not being pathognomonic of perforation of the organ. He detailed a case in which the sensation occurred, with every other sign of the accident in question, but to his surprise the patient recovered. He supposed it to be an hysterical affection.

PERFORATING ULCER OF THE STOMACH.

Mr. Hinds related the particulars of the following case:—

Sarah Ann Brandwood, aged 18, had suffered for a considerable period from pains of the stomach, for the relief of which she was in the habit of taking quantities of black pepper. It appears she was somewhat chlorotic, and the catamenia had not been present during eleven months. On Friday, October 27th, she was attacked immediately after her tea with vomiting, epigastric pain, and great depression of the vital powers. She was immediately brought home from her employment (that of a button-maker,) and after her arrival vomited several times. During the following night she suffered severe pain in the stomach, and could not sleep. I was called to see her about the middle of the next day. She was dressed, and sitting at the table down stairs. Her tongue was slightly coated with a brownish fur, and she was somewhat feverish. Some complaint was made of pain in the stomach. There was evidently some abdominal tenderness, though being dressed she was not very carefully examined in this part. The pulse was weak and small; bowels not open since yesterday morning. She had taken a teaspoonful of pepper, and some brandy, an hour or two previously.

R. Hydrarg. Chlor., gr. iij.; Pulv. Opii, gr. j.; Extr. Papav., q. s. Fiat pil. statim sumend. R. Liq. Ammon. Acet., oz. iss.; Sp. Æth. Nitr., dr. ij.; Mist. Camphoræ, oz. viiss. M. Cap. oz. j., quartis horis. Sinapismus abdomini applicandum.

Having gone to bed, by my direction, soon afterwards she became worse, and died at six o'clock the same afternoon.

Section cadaveris, thirty-seven hours after death. Stature short, well formed; mammary glands not much developed. Some tympanites of abdomen, at the most superior part, and which was a good deal distended. The abdomen having been cut into, serum and other fluid flowed out profusely, and about two quarts were removed from the cavity. Some vascularity was observed on the small intestines, with slight portions of lymph in some parts. In the anterior part of the stomach, and about an inch and a half below the cardia, a circular orifice was found, communicating with the interior, and from which half-digested food flowed freely. The size of the hole was about that of a large pea. Around the orifice, on the peritoneal surface, distinct appearances of inflammation existed. There was no adhesion whatever to any adjacent part. The whole parieties of

the stomach were hypertrophied, being at least twice their natural thickness. The mucous surface was almost uniformly pale, and the excavation at the seat of the peritoneal laceration did not exhibit any vascularity, or differ in appearance from the adjacent parts. The uterus was of the ordinary size, as seen in the virgin state. The ovaries were externally congested in patches, and contained several largely developed Graafian vesicles, and some appearances of a false corpus luteum. The other organs were healthy.

In regard to the pathology of this disease, as it exists in young women, who, there is reason to believe, furnish a considerable proportion of these cases, it may be well to ask whether any and what relation exists between these excavated ulcerations of the stomach and certain states of the uterus. In relation to certain anæmic states of the body, there appears to be little difficulty. Anæmia is well known to favour local congestion and subsequent chronic inflammation, and when it is considered that the stomach is so intimately connected with the uterus, by means of the sympathetic system of nerves, local congestion of the stomach must certainly be looked upon as by no means surprising. In this case it is rather remarkable that the whole parieties of the stomach were, at least, double the ordinary thickness, with scarcely any appearance of vascularity. There was no other ulcer nor excavation in any part in this case, which is somewhat curious; and the progress of the only one present, through the whole of the tissues down to the peritoneum, must evidently be in reference either to certain portions of food, or the action of the secretions of the stomach itself, on tissues which had become originally deprived of the mucous membrane, and which were not so capable of resisting that action as the mucous coat itself.

DISORGANIZATION OF THE KIDNEYS IN A PATIENT WHO DIED SUDDENLY.

Mr. Carter narrated the following case:—

J. R., aged 60, staying at a lodging house, and apparently in very destitute circumstances, without having made any complaint of ill health, except pain in the chest on the second night previous to death, was found dead in his bed.

Section cadaveris. The arms were bent on the chest, and the hands clenched, as though some severe pain in the chest had occurred at the moment of death; no pleuritic adhesion; lungs very large, healthy, with the exception of some emphysema in the free margins. Heart enlarged and soft in texture; valves healthy; left ventricle much enlarged, but the walls thin and soft; only a small quantity of fluid blood in the heart. Stomach empty, but very much congested, particularly the cardiac end. The kidneys greatly diseased; the right small, the left considerably enlarged; both permitted themselves to be squeezed out of their capsules, when the latter were opened, as though quite unconnected with them; they were of a deep red colour throughout, extremely soft and friable; the right retained little of the healthy structure; its tissue seemed almost disorganized; the left differed only in retaining one or two bundles of straight tubes, deeply

tinged with red, and distinguishable from the surrounding distension of the tissue. Decomposition was proceeding with great rapidity, although the *sectio cadaveris* was made soon after death.

**FEVER: SUDDEN DEATH IN FOUR WEEKS FROM
PROFUSE HÆMORRHAGE FROM THE BOWELS:
EXTENSIVE ULCERATION OF THE ILEUM.**

Mr. Brindley communicated the particulars of the following case:—

Mr. G., aged 55, a smith, robust, industrious, and temperate, of good general health, had an attack of diarrhœa in the second week of September, subsiding in two or three days. About the 17th, was seized with shiverings, followed by the ordinary symptoms of mild continued fever. No prominence was given to any particular symptom, except that there was much nervous depression and mental despondency. Some blood was observed in the evacuations once, about the end of the second week, with a tendency to looseness of the bowels. From the 6th to the 10th of October the bowels were not moved, and a dose of castor oil was given, after which he was moved two or three times daily. No delirium nor abdominal tenderness. (Mr. Williams and Dr. Fletcher had attended the case up to this time.)

October 13th. I first saw the patient with Mr. Thomas Chavasse. He made no particular complaint; was rather dull and heavy; had been a little deaf for the last few days; respiration somewhat accelerated; pulse 120, full, and of good strength; skin moist and perspiring; tongue covered with thick greyish fur at the middle, clean at the sides; bowels moved two or three times in the night: the last stool thin, dark, and contained several large, loose, black coagula; abdomen full, but soft, and not tender. Chest a shade duller throughout the right side, and respiration more feeble posteriorly, but there was no abnormal bruit; urine of good quantity, acid, turbid from deposit of urates, no albumen; head tolerably clear; no delirium, but a good deal of nervous depression.

14th. Comfortable night; three copious evacuations, fluid, but holding a large quantity of fecal matter, and containing no blood; feels relieved; tongue slightly aphthous; pulse less strong; no abdominal tenderness.

October 15th. Summoned in haste at 6 a.m., and found him dying. He had passed at twice about three pints of black blood, after which he became delirious, fainted, and was with difficulty got into bed; was pulseless, with cold extremities, slow respiration, and exsanguine state of lips and of general surface. He swallowed a little brandy, but expired in a few minutes.

Autopsy twenty-five hours after death.—Body well covered with fat. Head not examined. *Heart and lungs* sound, except some serous infiltration into the posterior part of the right lung. *Abdomen*: Liver of ordinary size, pale, soft in texture; gall-bladder contained a small quantity of thin, pale, yellowish fluid; spleen, pancreas, kidneys, stomach, duodenum sound; in the lower part of the ileum were numerous ulcerations, increasing in size and number as they approached the valve, where also were two or three small ulcers.

They measured about two feet from the termination of the gut, and were situated in Peyer's glands. At the upper part the enlarged glands were distinct; the solitary glands, here and there one, having in the centre a deep ulcer, in some very small, in others large; a few tumefied, but not ulcerated. In Peyer's glands, lower down, the sloughing process was more advanced, exposing large, red, irregular, and ragged surfaces, strewed over with small coagula. In several of these the sloughing had extended to the peritoneum, which externally had an opaque thickened appearance, from a deposit of lymph in small points, limited to the spots ulcerated, but nowhere adherent to adjacent parts. The ulcers did not extend beyond the valve. About half a pint of blood in the ileum and colon. Coats of the colon congested. The mesenteric glands opposite the ulcerations red and congested, with congestion of the vessels going to them. These effects were most marked opposed to the most advanced ulcerations. A long band, a prolongation from the great omentum, stretched downwards from the lower border of the stomach, and firmly adhered to the mesentery opposite the top of the sacrum.

(To be continued.)

Foreign Department.

ON THE SOURCE OF SUGAR IN THE ANIMAL ECONOMY.

By DR. BERNARD.

(Translated for the Provincial Medical and Surgical Journal,
from the Archives Générales de Médecine.)

Sugar is extensively distributed throughout the vegetable kingdom, but it exists also in animals. Vegetables do not find it ready made in the earth, but form it by some power of internal organization. Is it the same with animals? or is the sugar found in their bodies exclusively the product of their vegetable ingesta? This is the important question which it is our intention to submit to the test of experiment.

Sugar enters largely into the composition of the food of animals. The kinds of sugar are,—1st, Cane sugar, such as is found in the sugar cane, beet-root, carrots, &c. 2nd, Grape sugar, such as exists in grapes, and other saccharine fruits. Fecula should also be considered as saccharine matter, inasmuch as it is convertible into low sugar during the process of digestion. 3rd. Sugar of milk, which is found in the milk of animals.

This is not the place to trace the distinctive characters of these forms of sugar, nor to determine the alternate changes which they undergo in order to become subservient to nutrition. I need only state, that as certain alimentary substances are known to furnish considerable quantities of sugar, we may consider them as the source of the saccharine matter which we discover in the blood or other animal fluids. It is admitted that sugar is to be found in the healthy blood, after the ingestion of sugar, or matters convertible into

sugar. But chemical facts teach us on the one hand, that starch is the only principle which is convertible into sugar, and on the other hand, in the belief that the animal economy has not the power to originate a principle, but only to transform those which are presented by the vegetable kingdom, it has been denied that the animal organism can form sugar, and the only power recognized is that of destroying and eliminating it. The facts which will be developed in the following essay shew us that such an opinion is not warranted by physiology:—

FIRST SERIES OF EXPERIMENTS.

It has been observed, that during the digestion of saccharine or amylaceous matter, the blood contains sugar, and it has thence been concluded that the sugar is furnished by the aliments. This result of experiment taken alone is exact, but the experiment itself is incomplete, and the conclusions therefore false, as will be seen.

1st *Exp.* I injected thirty grains of starch dissolved in a pint of water, into the stomach of a rabbit which had eaten oats and carrots. Five hours after, the animal was destroyed in the usual way, and thirty grains of blood from the heart collected. After coagulation, sugar was distinctly found in the serum. The stomach and intestines contained sugar arising from the carrots and the transformation of the farina.

2nd. *Exp.*—A strong dog was destroyed five hours after eating 300 grains of the jelly of starch. The serum of the blood taken from the heart contained a notable quantity of sugar. The contents of the stomach were acid and contained no sugar; those of the intestines were alkaline and strongly saccharine.

3rd *Exp.*—A dog ate plentifully of sheep's head and was killed after seven hours. In the serum of the blood sugar was distinctly found. No sugar was found in the intestinal canal.

4th *Exp.*—A dog was killed after fasting two days. Sugar was unequivocally found in the serum.

The above experiments were repeated several times and always with the same results. The general fact established is readily seen,—viz., that sugar is constantly present in the blood of animals, whatever has been the nature of their food.

SECOND SERIES.

Whence is the sugar derived in the case of the animals fed on meat, and in that which had not eaten for two days previous to death? This is the question for the solution of which fresh experiments are required. It may be fairly presumed that the sugar was not formed in the heart, but had been transported thither from some other parts of the body. To determine more exactly the locality of its formation. I performed the following experiments:—

1st *Exp.*—A large strong dog being killed seven hours after a hearty meal of cooked meat and bones, digestion was found to be in full operation, and the gastrointestinal circulation, and chyloferous ducts fully distended with their respective contents. I obtained,—1st, some blood from the junction of the splenic vein, with the vena portæ; 2nd, some chyle from the

thoracic duct; 3rd, blood as before from the cavities of the heart. I then carefully separated the contents of the stomach and bowels, and tested each separately for sugar with the subjoined results:—

1. The alimentary matters of the stomach and small intestines had an acid reaction, and afforded no evidence of the presence of sugar.

2. The milky serum afforded by the coagulation of the chyle was also destitute of sugar.

3. The blood of the vena portæ being allowed to coagulate, the serum was slightly opalescent and alkaline; I distinctly ascertained the presence of a large quantity of sugar.

4. The blood from the heart also presented sugar, but in less abundance.

The experiment was repeated several times, and with always the same result, but without my being able to comprehend how the portal blood should contain so large a quantity of sugar, while none existed in the small intestines. Reflecting, however, that this matter must be derived from some neighbouring viscus, I proceeded as follows:—

Having quickly destroyed a dog which had some hours since fed on matters destitute of sugar or fecula, I opened the abdominal cavity, and placed ligatures,—1st, on the branches of the mesenteric veins, close to the small intestines; 2nd, on the splenic veins, close to the spleen; 3rd on the pancreatic veins; 4th, on the trunk of the vena portæ as it entered the liver. I then collected blood from each of these sources, and examined it. 1. Sugar was not found in the blood of the intestines, nor in their contents. [The original states that sugar *was* found, but this is evidently an error of the press, as appears from the context.—*Trans.*] 2. Sugar was not present in the blood, either of the splenic or pancreatic veins. 3. The blood of the portal veins contained a large quantity of sugar, as did also the tissue of the liver itself.

It was thus made evident that the liver was the source of the saccharine matter. But it must be asked, how is it that sugar is found in the portal veins, for supposing it to be formed in the hepatic glandules, it should be carried into the general circulation by the hepatic veins, and not flow back into the portal branches. This reflux is, in my opinion, easy to be understood, for, in fact, the circulation in the porta is mainly effected by the pressure of the abdominal parieties during life; if, therefore, the pressure be removed as in opening the abdomen, there would immediately be a reflux from the absence of valves in the portal system.

We have ascertained, by the above experiments, that sugar is found in the liver, and is carried into the general circulation by the blood of the hepatic veins, the reflux into the porta being accidental; but we regard this discovery to be so important, that we think it right to state the processes employed in the investigation, in order that others may confirm or confute our conclusions, by following in our footsteps.

TESTS FOR SUGAR IN THE LIVER ITSELF.

A portion of liver is to be beaten in a mortar, and then boiled in a small quantity of water, and filtered.

The filtered liquid possesses all the properties of a saccharine fluid. It becomes darker on boiling with liquor potassæ, and it reduces the double tartrate of potass and copper. If yeast be added at a certain temperature, fermentation ensues; if the fluid be distilled after fermentation, alcohol may be obtained.

The attempt was made to procure sugar in substance by operating on large quantities of liver, but although a fluid of syrupy consistence was obtained, crystallization did not take place.

The recognition of sugar in the blood is a very simple affair; the blood is allowed to coagulate, and the serum placed in a tube furnished with a stopper; to this is added a sixteenth in bulk of the tartrate of copper and potash, and boiled, when a quantity of the salt is reduced, proportionate to that of the sugar present. By this process the smallest traces of saccharine matter may be detected. Both in this test, as well as that by fermentation, it is necessary to operate on the serum while it is fresh, as sugar is rapidly decomposed spontaneously.

We have now traced the sugar of animals to the liver, but we have further to determine whence it is derived. Two suppositions may be entertained; either it results directly from a transformation of certain elements of the liver, or it is derived from the food. It may be said, in fact, that the animals which had been fed exclusively on animal food, or starved, might have eaten fecula or saccharine food the few days previously, and that the sugar thence derived had accumulated and been detained in the liver; and it might be added in support of this view, that the liver is known to retain arsenic and other poisons for a length of time. Without actually denying this view, the following experiments would seem to oppose it:—

1st *Exp.*—A full-grown dog was starved for eight days, and then fed abundantly on cooked meat for eleven days; after this he was destroyed. The blood contained an abundance of sugar. This experiment was repeated several times, and certainly it would appear probable, that sugar derived from food, given antecedently, would have been eliminated after a lapse of nineteen days.

2nd *Exp.*—A rabbit, after a meal of carrots, was subjected to the division of the pneumo-gastric nerves. He was found dead seventeen hours after. *No sugar was found in the blood or liver.* This experiment was repeated with similar results. In both animals the bile, which is generally alkaline, was found to have a distinctly acid reaction.

This effect of division of the pneumo-gastric nerves is remarkable. As a further proof that sugar is found independently of food, I may state that I have found it in large quantity in foetal calves.

From the above facts the author draws the following conclusions:—

1. That diabetic sugar is a normal ingredient in the blood and liver of animals.
2. That the formation of sugar takes place in the liver, and independently of saccharine or feculent food.
3. That this formation of sugar commences before birth.

4. That it is allied to a state of integrity of the pneumo-gastric nerves.

[We have translated this memoir entire, considering it to be very important in its bearing upon the pathology and treatment of diabetes, many of the received doctrines concerning which it must, if verified, tend to subvert.—FOR. ED.]

THE GENERAL MEDICAL ANNUITY OR RELIEF FUND.

TO THE MEDICAL PROFESSION.

Gentlemen,—Throughout society, amongst the arts and sciences, and in every trade and profession, there exist sentiments of mutual and independent succour and assistance, the medical profession alone excepted. There is scarcely any other community, the constitution of which does not embrace a provident and benevolent establishment. How, then, it may be inquired, arises this strange anomaly? Why do the members of the medical profession alone neglect the natural and moral responsibility of anticipating the risks and uncertainties of life and health? Why, of all mankind, are they regardless of the ills to which flesh is heir? Is it because, as a community, they are provided for the downfall of life? Do they enjoy the smiles of fortune without dreading her frowns? Are they collectively possessed of wealth and affluence? Are they competent to command the comforts of life, when age and infirmities press upon them? Can they meet calmly their incompetency for labour and exertion?—anticipate without misgiving and anxiety their second childhood?—and insure to those whom they may leave behind—those who are bound to them by ties the most natural, sacred, and inviolable,—those whose maintenance has devolved upon them,—can they secure to them a defence against the cankering cares of the world?—nay, can they even insure to them the necessities of life, independently of fortuitous or eleemosynary aid? I solemnly appeal, not only to the members of the profession in the United Kingdom, but to our common fraternity throughout the world, and ask,—can you do these things? The history of the profession, the records of mortality, and the experience of mankind, warrant me in saying, you cannot. Surely, then, it becomes us, as a community, seriously to consider these things. It is the bounden duty of every member of the profession to realize this great—this paramount design. Doubtless there are amongst us some few who are what is termed independent of the world. There are those who can allot a portion of their income to the security of ease and comfort, during the infirmities of age,—who can soothe the downhill of life, and soften the passage to the grave; but they constitute an unimportant minority;—they are, in connection with the whole body of the profession, insignificantly small. In Great Britain alone, upwards of thirty thousand medical practitioners toil and wear out their lives, (rendered infinitely shorter by the nature of their employment,) and not more than two or three per cent. of this number could answer in the affirmative the simple but momentous questions raised above. What then must be the prospects and anticipations of men whose occupation constantly associates them

with disease and death,—men whose daily labour embraces the public good,—whose time is devoted to the amelioration or removal of the miseries of mankind,—whose talents render essential aid to benevolence and humanity, and whose services are alike implored by all,—from the monarch on the throne, to the mendicant at the door.

Up to the year 1845, when the grand project of a General Medical Annuity or Relief Fund was originated, through the zeal, the talents, and the philanthropy of Mr. Daniell, of Newport Pagnell, the great body of the medical profession had no efficient available means of anticipating the calamities of time; they had not an opportunity of providing against the uncertainties and casualties of life and health. But the General Medical Annuity or Relief Fund is still in its infancy—is comparatively unknown to the great mass of the profession, and unappreciated by the majority of those who are acquainted with its existence. Shame on the apathy which attaches too frequently to those who personally feel not the necessity of provident forethought; whilst (discreditable to the affluent of our brethren,) the noble, the benevolent, the magnanimous project of securing the well-being of our community is, by too many amongst them, suffered to languish, and its claims are disregarded. It is not, however, out of place to remind, both frequently and forcibly those to whom fortune has been propitious, that their guardian goddess is fickle as well as kind; that riches oftentimes make themselves wings, and flee away; and, judging from the great and universal commercial crisis which at present prevails, it is no Utopian doctrine to assume, that the year 1848 will have left many in poverty and distress, whom it found in happiness and prosperity. To every member of our profession, then, the duty and the responsibility attaches, of furthering the philanthropic project of Mr. Daniell. Every individual in the community is appealed to by the obligations of society, by the claims of sympathy, by the dictates of nature, by the widow's tears and the orphan's cries, to establish and support the General Medical Annuity or Relief Fund. Nor do its claims to support rest alone with the profession; the public owe largely, owe essentially, to the art of medicine. The community in general derive important and indispensable services from our profession. Without health, paltry indeed is the attainment of riches. Deprived of the power of enjoyment, what avails the possession of wealth. That the public is not wanting in acts of charity and benevolence, the enormous sums annually appropriated to scientific and other institutions, abundantly testify; that certain services merit and meet their reward, witness the contributions in aid of the families of those whose lives have been spent or sacrificed in the defence of their country. If an appeal be made to the public, in behalf of a literary or charitable undertaking, it is immediately responded to in a manner becoming a generous and enlightened nation. If the honour of an individual, whose country has derived amusement or pastime from his talents or acquirements, demand the accumulation of hundreds or thousands of pounds, the fund is raised with gratitude and alacrity. But that the claims of the medical profession, for themselves or their families, are totally disregarded, both by

the public and the State, is a painful fact, established by every day's experience.

If a member of our profession becomes disabled, or dies, how unwilling are mankind to acknowledge the claims of his family, even should his disability or death have been occasioned by his devotion to the public good. The case of the late Dr. Lynch is a melancholy and reproachful instance. Seeing, then, that the community at large evince no sympathy with our widows and orphans, that the public disavows its obligations for our services, and disregards our claims, does it not become us, as rational and responsible beings, to secure, by union and forethought, a provision and defence against the contingencies of life? Is it not our duty to provide for those who look alone to us for succour and support, whilst life and opportunity allow? Be it, then, the determination of every one of you, gentlemen, to realize these important designs, either for yourselves or your professional brethren. Let us set our shoulders to the wheel with energy and determination, and in the might and majesty of union our success is certain.

I am, gentlemen,

Your obedient faithful servant,

L. F. CUMMING.

Stokesley, January 9, 1849.

CHOLERA ASSURANCE SOCIETY.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

I have sent you some rules and regulations for a "Cholera Assurance Society," a sanitary movement, on the vastly abused and ill-understood "*self-supporting principle*," and which I hope the medical public are now better prepared to appreciate than they were thirty years ago, when I first broached it.

RULES AND REGULATIONS.

"That each head of a family subscribing any sum from sixpence to five shillings weekly, shall be allowed twelve times the amount of such subscription daily, from the time any one or more of his or her family (including servants,) shall be attacked by Asiatic cholera, until the death or convalescence of the patient.

"That there be allowed for the funeral expences of each parent of a family, subscribing any sum from sixpence to one shilling weekly, the sum of £3; and where such subscription shall exceed one shilling weekly, £5; and for each child or servant of a subscriber's family, the sum of £2, without any reference whatever to the amount of subscription.

"That no subscriber, or any member of his family, shall be entitled to any benefit or relief from the Association after such subscriber shall have made default in payment of his weekly subscription, unless he shall within two days after demand by the Collectors, or one of them, pay the same and all arrears then due.

"That whenever the resident medical practitioners of Southam shall certify to the Committee under their hands that they are of opinion the Association may be safely dissolved, the same shall, *ipso facto* cease, and the unappropriated funds then in the hands of the treasurer—subject to any existing liabilities of the Association—shall be returned to the subscribers, in proportion to the total sums respectively subscribed by them.

"That it be a strong recommendation from this Committee to the General Association, that in case this parish

shall in mercy escape altogether from this alarming scourge, one moiety of the funds unappropriated be devoted to some charitable purpose, as a thank-offering to Almighty God for his great and undeserved mercies to the inhabitants of this parish.

Similar rules to these were successfully tried in 1832. At that time, many fathers of families, seriously impressed with an awful sense of danger from the prevalence of cholera throughout the kingdom, and which they were told, might reduce many of the most excellent and industrious tradesmen, mechanics, and labourers, from comparative respectability and comfort to the greatest distress and poverty, agreed to unite in the spirit of brotherly love and christian regard for each other, and to combine their resources together, thereby hoping to remedy such of the consequences of the complaint as were within their power. At that time the cholera was introduced twice; once into the town, and once into a village, by a boatman's family, about two miles from us, and three persons lost their lives, though it never extended from the place to which it was brought. I attribute this checking of its course mainly to the public confidence the "Cholera Assurance Society" gave to the medical men, and in submitting to have those things done for them good naturedly and voluntarily, which I am sure they would have at least grumbled at if it had been done by Act of Parliament.

For instance, when a case of cholera was reported to us, I went with Mr. Gardner, (now of Brighton,) and we caused the door of the cottage (a barber and tripe-dresser's,) to be surrounded by hurdles, and gave strict orders to have no person, excepting the doctors and nurse, to visit the house. We also ordered a fire of shavings, &c., to be kept burning before the door, within the fence, for without entering into any question of its contagiousness, or mode of travelling, whether by steam or electricity, we thought it good sense to rarefy the atmosphere before the door, and so dilute and carry away anything offensive upwards. It succeeded, for though the patient died, there was no extension of the disease.

It may be encouraging to add, that by placing the money in the Savings' Bank, as it was paid in weekly, and by allowing the interest to accumulate, with the aid of a donation, we were enabled, some months afterwards, to restore to each of the subscribers the entire amount of his accumulated payments.

I have also sent you an address to the labourers, &c., which was eagerly purchased, and proceeding from a medical man who was known to them, I think had more influence over them than dry official papers from a remote Board of Health could be expected to have. I am afraid it is too long for insertion in your Journal, but something of the kind issued by the local friends of the people, would be more useful than anything likely to come from the great crowned image at Somerset House, whose little toe of iron and miry clay, at Southam, would trample on any man who should seek to improve the condition of the honestly independent labourer.

I remain, Sir, your humble servant,

H. L. SMITH.

Southam, Warwickshire, May 20, 1849.

NOTICE OF W. HENCHMAN CROWFOOT, ESQ., F.R.C.S., OF BECCLES.

[We are gratified to be able to comply with the wishes expressed by several members of the Association, for some notice of the late Mr. Crowfoot, of Beccles. The following is a brief but authentic sketch of the medical career of our lamented Associate.]

Mr. Crowfoot was born September 9th, 1780, at Kessingland, a village on the Suffolk coast, where his father occupied a large farm. He had the misfortune to lose his mother, the daughter of the Rev. J. Henchman, in his infancy, but at an early age he was placed under the charge of the Rev. W. Clubbe, Vicar of Brandeston, who was married to his mother's sister. Mr. Clubbe being an elegant Latin scholar, he there imbibed a strong taste for classical literature.

In 1794 he was apprenticed to his uncle, Mr. Crowfoot, of Beccles, who treated him with the affectionate kindness of a parent. In 1799 he removed to London, and entered as a pupil at the borough hospitals, under Mr. Cline and Mr. Cooper, the latter of whom ever entertained for him a high regard, which was proved by several marks of attention in after life. In Mr. Cooper's work on "Dislocations," he speaks of him as one "who, to high professional skill, adds all the amiable qualities which can become a man."

On leaving the hospital he hoped, by the assistance of Mr. Cooper, to obtain a medical appointment in India, but not succeeding in this, he eventually settled in Framlingham, a small town in Suffolk. Here he did not readily obtain so much practice as he desired, and at the suggestion of his uncle, Mr. Crowfoot, he removed in 1803 to Beccles.

In 1805 he became his uncle's partner, and his career was thenceforth marked by high professional credit and success. It was in the December of 1805 that he accidentally met a party bearing the body of a soldier, who had been thrown on the beach at Kessingland, and lain for several hours apparently dead. Finding that the præcordia still retained some warmth, he caused the body to be carried to a house, and persevering in the means of restoration which his professional skill suggested, he at length revived the sufferer. For this action the Royal Humane Society awarded him a silver medal at their next annual meeting.

When the new charter was conferred upon the College of Surgeons, the Council of that body honoured him by selecting him as one of the original 300 fellows.

Actively engaged in the pursuits of a very extensive practice, Mr. Crowfoot had but little time to devote to writing on medical subjects; but he occasionally published in the leading periodicals of the day, any remarkable results of his own experience. All his papers were characterized by strong sense and practical usefulness. He pointed out the connection between rheumatism and carditis before that connection was so much insisted upon as at present. He published an account of the successful employment of extension in a case of fractured spine, shewing the value and importance of that mode of treatment in cases which are too often regarded as

hopeless. He also published several papers on subjects connected with puerperal diseases.

The peculiar characteristic of Mr. Crowfoot as a medical practitioner was the accuracy of his diagnosis, he usually apprehended at once the distinguishing features of a disease. His treatment was simple. He ever aimed to attain the object he had in view by the most gentle remedies. Throughout life he was an ardent pathologist, and lost no opportunity of confirming or correcting his views of a case by a *post-mortem* examination, indeed his life fell a sacrifice to his zeal in the pursuit of pathology; for, in consequence of opening the body of a patient who died from a malignant form of typhus fever, he contracted the disease, and expired on the 13th of November, 1848, after an illness of only four days.

Few country practitioners have enjoyed so large a share of public confidence as Mr. Crowfoot. Though his professional ability was much above the average, this was even less esteemed than his high integrity, urbanity, and gentlemanly conduct. His medical brethren ever found comfort and aid in his judicious advice as a consulting surgeon, while his private patients experienced in his delicate, gentle, and soothing attention, that tenderness which relieves so effectually the bitter trials of anxiety, pain, and sorrow. Whether called to the cottage or the mansion, he was alike watchful, and earnestly anxious to relieve. High and low, rich and poor, will long regret in his death the loss of one who was in an unusual measure their common benefactor and friend.

Medical Intelligence.

TESTIMONIAL TO DR. PARIS AND MR. FONBLANQUE.

A service of plate and one hundred guineas have been awarded by the Council of the Society of Arts to Dr. Paris, President of the Royal College of Physicians, and to Mr. Fonblanque, for their joint work on Medical Jurisprudence.

APPOINTMENTS.

William Heane, Esq., has been appointed Surgeon to the Suffolk General Hospital, by purchase, in accordance, as it appears, with the rules of the Hospital.

Farquhar Milne, Esq., has been elected one of the Surgeons to the Chorlton-upon-Medlock Dispensary, Manchester.

Daniel Blair, Esq., M.D., has been appointed Surgeon-General for the colony of British Guinea.

SOCIETY OF APOTHECARIES.

Gentlemen admitted Licentiates Thursday, January 18th:—William Griffiths, Standish, Lancashire; Thos. William Houchen, Werchem Hall, Norfolk.

Gentlemen admitted Licentiates Thursday, January 25th:—John Wilson; William Murthwaite Thompson, Lambeth.

OBITUARY.

Died, January 16th, at Worthing, aged 71, Jacob William Robins, Esq., M.R.C.S.

January 19, at Dorking, aged 82, Isaac Chaldecott, Esq., formerly Surgeon to the Garrison of Portsmouth.

January 23rd, at Hastings, aged 46, Henry Colebourn, Esq., M.D., of Stockwell Villas, Clapham:

January 24th, at Aberdeen, of fever, aged 33, William Mackinnon, M.D., Fellow of the Royal College of Physicians of Edinburgh.

January 31st, at Grange Terrace, Brompton, aged 33, Dr. George Fownes, F.R.S., Professor of Practical Chemistry at University College, London.

Lately, at Riggsville, of fever, Dr. Cornwall, Superintendent of the Killucan Dispensary.

BOOKS RECEIVED.

Surgical Anatomy. By Joseph Maclise, Surgeon. Fasc. I. London: Churchill. Folio. Plates.

Pathology of the Human Eye. By John Dalrymple, F.R.C.S. Fasc. I. London: Churchill. 1849. 4to. Plates.

An Essay on some of the Most Important Diseases of Women, &c. By W. Jones, M.D., Physician to the Free Hospital for Women and Children, &c. London: Bailliere. 1848. pp. 41.

The Examination of a Rejected Candidate at the Royal College of Physicians of London, December 21st, 1848. By Edwards Crisp, M.D., M.R.C.S. L.A.C., &c. London: Churchill. 1849. 8vo. pp. 62.

Medical Portraits:—Dr. Forbes; Dr. G. Budd.

The London and Provincial Medical Directory—1849. London: Churchill. pp. 532.

PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION.

NOTICE TO MEMBERS.

Gentlemen who have not yet paid their subscriptions, are respectfully requested to bear in mind that the subscriptions become due in advance on the 1st of January of each year. Those Members who are in arrear will materially facilitate the business of the Association by immediately forwarding the amount, as the circulars applying for arrears will shortly be issued.

ROBERT J. N. STREETEN,
Secretary.

TO CORRESPONDENTS.

Communications have been received from Mr. Spooner; Mr. Humphry; Mr. H. Dayman.

It is requested that all letters and communications be sent to Dr. Streeten, Foregate Street, Worcester. Parcels and books for review may be addressed to the Editor of the Provincial Medical and Surgical Journal, care of Mr. Churchill, Princes Street, Soho.

PROVINCIAL MEDICAL & SURGICAL JOURNAL.

A COURSE OF LECTURES ON SURGERY,

DELIVERED IN THE

MEDICAL SCHOOL OF CAMBRIDGE.

By GEORGE MURRAY HUMPHRY, Esq., Downing College, Surgeon to Addenbrooke's Hospital.

LECTURE III.

General Symptoms of Inflammation, analogous to Local; Changes in Blood; Cause of Buffed Appearance, and its Value as a Symptom; small Size and Firmness of Clot:—Other Changes in Blood; their Relation to the Fever; Resemblance of Inflammatory Blood to that of Pregnant Females; the preliminary general Depression, resulting probably from corresponding Condition of Part about to be inflamed:—Treatment of Inflammation; Bleeding; quality of Pulse indicating need of Bleeding; consequent Reaction; Period at which Bleeding should be adopted; Local Depletion near the inflamed Part, but not from the inflamed Skin:—Mercury and Opium, Indications for and against their Use.

The presence of local inflammation, especially if it be severe, extensive, or situated in an important organ, is soon followed by a train of constitutional symptoms analogous to those occurring in the inflamed part, and seeming to result from an extension of the inflammatory disturbance to the system, much in the same manner as it spreads from point to point, at the immediate seat of the disorder. The increased activity of the vessels has its analogue in the general excitement of the vascular system,—in the rapid and forcible action of the heart,—in the full, hard, and bounding pulse. The concomitant headache, soreness, or even tenderness of the whole body, the restlessness and irritability, show a disturbance of the nervous system, corresponding with the local pain. The sense of weakness and inability to make any exertion, the hot dry skin, the loaded tongue, the thirst, costive bowels, the scanty urine loaded with lithates, together with the alteration and diminution of the other excretions and secretions, are additional evidences of a disordered state of the constitution, bearing much resemblance to the local disease. The comparison derives still further force from an examination of the changes which are found to have taken place in the blood circulating through the body. These are of sufficient importance to require our careful attention, inasmuch as the question of the existence of inflammation, and the proper treatment to be pursued, are often determined

by the appearance of the blood drawn from the body, when the other indications would have left us doubtful of the real nature of the malady.

In blood drawn from a healthy person, the red globules are observed in two or three minutes to collect into heaps or rolls, with their flat surfaces approximated like coins laid upon one another, at the same time the blood becomes a little stiff, or set, from the commencing coagulation of the fibrin, so that it forms a loose sponge-like structure, entangling the little masses of globules and the serum in its substance. The globules are distributed almost equally throughout this soft jelly-like substance, giving it an uniform red colour; it occupies about the same space as the fluid blood had done before coagulation commenced, and adheres to the sides of the vessel into which it was drawn. During the further coagulation or contraction of the fibrin its particles approach more closely to one another, and squeeze out the serum from between them without displacing the globules, so that in a short time the contracted fibrin and red globules forming the clot are found separated from the sides of the vessel, and floating in the serum expressed from them.

The red globules are comparatively heavier than the fibrin, and would sink to the bottom of the clot if their descent were not arrested by the coagulation of the fibrin. This actually does occur if by any means their relative weight is increased, or the coagulation of the blood is delayed beyond its usual time, both which effects are produced by inflammation; for, in the first place, the red globules of inflamed blood adhere together so quickly, that they are found to have clustered into little masses before the blood can be placed under the microscope, and, as a necessary consequence, they fall through the blood more quickly than in the healthy state; and, secondly, the specific gravity of the fibrin is diminished, and its coagulation takes place more slowly than under ordinary circumstances. Owing to the combined influence of these changes in the qualities of the blood, the red globules subside towards the bottom of the clot, leaving the upper part of a lightish brown or buff colour. The coagulation and contraction of the fibrin continuing takes place most completely where it is least impeded by the presence of red globules, so that the upper part of the clot is reduced to a smaller size than the rest of its substance, and from the same cause becomes cupped on its surface, and puckered at its edge. The blood is now said to be buffed and cupped.

That the slowness of coagulation is an important

element in the formation of the buffy coat is proved by the appearance of the coagula found in the heart and great vessels after death. The setting of the blood, when the circulation has ceased, takes place slowly, in consequence of its being still subject to the vital properties of the tissues which remain for a time after the general death of the body; the red particles subside, and the upper part of the clot, that, for instance, which occupies the right auricle of the heart, is generally found to be composed of buff-coloured fibrin, with a small quantity of serum included in its reticular substance. Other causes also which retard the coagulation of the blood may give rise to the formation of the buffy-coat, and it occurs naturally in the blood of some animals,—as the horse.

But that the buffing and cupping of the blood in inflammation do not depend merely upon the slow coagulation of the fibrin, is also proved by their being occasionally observed in blood which has coagulated quickly, and they are sometimes absent when coagulation has been delayed thirty or forty minutes after its withdrawal from the body. In those particular cases, in which coagulation occurs very imperfectly, or not at all, after death, the subsidence of the red particles does not appear to take place, and the blood presents a uniform red colour. (I merely mention these varieties, without attempting to explain them.) The buffing and cupping of inflammatory blood are dependent, no doubt, on that alteration in the properties of the red particles which accelerates their coalescence, in addition to those other changes in the blood which increase their relative specific gravity, and modify the rapidity and force of the contraction of the fibrin.

There is also another cause, occasionally giving rise to a buffy appearance of the upper part of a clot which must be taken into consideration in estimating the value of this symptom. I refer to the presence of an unusual quantity of white corpuscles. When the constitutional symptoms of inflammation have arisen, these bodies are found circulating in large quantities through the body, just as a greater number of them were observed in the inflamed part. They are of lower specific gravity than the rest of the blood, so that while the red corpuscles sink to the bottom, they rise to the top, of the clot, and are found in greatest numbers in the buffy stratum. They do not, at this part, exist in such great numbers as do the red corpuscles at the lower part of the clot, or they would in the same manner interfere with the contraction of the fibrin, and prevent the cupping. Under certain circumstances, when the formation of blood is going on quickly, as after a full meal, or in consequence of an unusual call upon the nutritive functions during pregnancy, the healing of a large wound, after loss of blood, and so on, these white corpuscles are present in great abundance, and if blood be drawn at such time, they may rise to the top, and form a buffy coat. It happens that their disposition to do so is, in some of these conditions, favoured by the coagulation of the blood being a little slower than usual. Unless aware of this fact, you might occasionally be led into error by too implicit reliance on the buffy coat as an indication of the

presence of active inflammation. It is well also to bear in mind, that although the buffy coat observed on the first bleeding may result from the presence of inflammation, the same symptom may, on subsequent occasions, depend upon the increased number of white corpuscles taking place to make amends for the former loss of blood.

Happily there is another distinguishing feature of inflammatory blood which is even more characteristic, and certainly is of more practical value, than the buffy coat. I mean the increased contractile force of the fibrin which occasions the clot to be small and tough, not easily penetrated by the finger, and gives rise to the formation of the cupped condition of the surface, for, I should say that the buffy coagula occurring under the circumstances just mentioned are very rarely cupped. This increase of contractile force is generally proportionate to the slowness of the coagulation, and is most marked in vigorous persons, and in acute attacks of inflammation. The small tough clot is a more important sign than any other condition of the blood in the treatment of inflammatory fever; it marks the severity of the disease and the powers of the patient—the necessity for active treatment and ability of the patient to endure it.

The inflammatory blood presents the appearances just described, more or less distinctly, according to the degree in which the blood has undergone the changes which occasion them. In some cases there is a complete subsidence of red particles from the upper part of the clot, which is small, firm, deeply cupped, and puckered on the surface. Such well-marked characteristics in the clot generally accompany severe fever in a vigorous constitution, associated with inflammation of a serous or fibrous membrane. In other cases the coagulum is larger and less firm, the buffy coat is thin and easily broken, the subsidence of the red globules and the contraction of the fibrin are less marked, and the accompanying inflammation is less violent, or may be seated in a mucous membrane.

The coagulation of the blood, though a vital process constituting the first stage of organization, and resulting from the inherent tendency of its particles to unite together and form a tissue, is, in the living body restrained by some higher counteracting influence, which suffers it to take place only in subservience to the nutrition of the tissues. Except in the case of inflammation, when the independent powers of the blood seem to be greatly increased, and in extravasations of blood, coagulation does not occur till this restraining influence is removed by the death of the body or the abstraction of the blood from it. When coagulation does take place, it will do so in greatest perfection, and most slowly, where its vital energies are best preserved, as in the body after death, or when it flows from the living body in a full stream and is at once received into a deep vessel. By taking such precautions we give the most favourable opportunity for the manifestation of the characteristics of inflammatory blood, we remove it from the controlling influence of the tissues without diminishing in any great degree its own vitality, so that it is freed from restraint and exhibits

the changes which it has a tendency to undergo. If, on the other hand, its vitality be much lowered, by exposure to the air, as when it falls from a considerable height in a small stream, by its reception in a flat or very cold dish, or in other ways, coagulation is rapid and imperfect, and the buffy coat is less likely to be observed. A still further reduction of its vitality will prevent the coagulation altogether. Examples of this are furnished by cases of death from lightning or severe injuries to the nervous centres, when the vitality of the whole body, its fluid as well as its solid components, appears to be instantaneously destroyed.

Further important changes in the general mass of the blood corresponding with those observed at the seat of the inflammation, are the increase in the quantity of the fibrin and the diminution of the red globules.

These are found by M. Andral to be proportionate to one another and to the activity of the local disease rather than to the severity of the febrile disturbance. Indeed the experiments of that physician serve to shew that in common fever the amount of fibrin is diminished, the number of red particles undergoing no material alteration; and that any increase in the fibrin during fever is almost always referable to the development of some local inflammation. He, accordingly, attributes the increase of the fibrin in inflammatory fever to the changes taking place in the inflamed part; and the coincidence observable between the increase and diminution of the febrile symptoms, and the increase and diminution of the fibrin, he refers to the dependance of the fever and the changes in the blood on the same cause, viz., the extent and intensity of the local disease.

The several changes observable in blood drawn from the system during inflammatory fever, the diminished quantity of red, and the increase of white globules, the corresponding increase of fibrin, with its altered qualities, inducing slow coagulation with a firm clot buffed and cupped, together with the disposition of the red globules to adhere quickly into rolls and masses, correspond precisely with the condition of the blood at the inflamed part, and seem to originate there. Probably the altered fluid circulating thence contaminates the remainder of the blood, spreading over the system the flame that had been communicated to it at the seat of the disease.

Whether the inflammatory fever depends upon this morbid condition of the blood circulating through the system it is not easy to decide. The observation of M. Andral, that the changes in the blood correspond with the local disease rather than with the fever, and that they do not accompany the latter unless some local inflammation exists, do not favour such a supposition. It is, perhaps, more probable that the extension of the inflammatory condition from point to point, and from a part to the whole system, depends upon certain properties in the disease of an assimilative nature, aided by that particular relation between the several parts of the system which we call sympathetic, that interweaving of function and universal harmony of its several members, which does not permit one part of the body to suffer without detriment to the whole.

I have already alluded to the fact that the buffy condition of the clot and the increase of the white globules are often observed in the blood of the pregnant female. M. Andral finds that the amount of fibrin is also increased and that the red globules are deficient in the later periods of pregnancy. This correspondence in the condition of the blood at the time when nature is putting forth her best energies to furnish material for the development and growth of another being, with the changes which it undergoes in inflammation, is an interesting feature in the physiology of both processes, and is thought by M. Andral to have some relation to the occurrence of those special accidents, mostly of an inflammatory nature, which so frequently affect females recently delivered.

The excitement of inflammatory fever is almost always preceded by symptoms of constitutional depression. The feeble pulse, chilly sensation, cold extremities, loss of appetite, pain in the loins, general languor and feebleness, indicating a depressed condition of the circulatory and nervous systems, are the usual precursors of the febrile symptoms which seem to follow as a reaction from them. This general depression, the earliest in the train of symptoms, is a very important one, warning us of the forthcoming mischief, which is, for the most part, proportionate to it in severity. A sudden and violent rigor, with pale ghastly countenance, sunken eyes, feeble rapid pulse, cold clammy skin, and sense of sinking are fearful symptoms to witness, and they portend serious evils. The patient may die outright, the great organs being unable to stand against this depression of their vital powers; or he may linger on for some days, unable to rally, and may sink at last under its influence. Commonly it is the forerunner of a violent inflammatory attack, which quickly follows. The less severe inflammatory affections are preceded by symptoms of a similar kind, but less alarming; the patient feels unwell, chilly and languid, he cannot get warm and is unfit for work for a day or two before the manifestation of the disease, of which this condition is the forerunner. So constant is this preliminary train of symptoms in one form or other, and so nearly proportionate is it to the ensuing illness, that when summoned to a patient at the commencement of an inflammatory attack, we may often form a tolerably correct estimate of the probable severity and duration of the disorder by the preceding chill; and we are often relieved from the apprehension excited by a febrile attack, when we discover that it had not been preceded by sufficient evidence of constitutional depression to have attracted the patient's notice.

In forming an estimate of the value of this symptom, we must not forget the very different degrees in which the nervous systems of different individuals are wont to respond to impressions made upon them. The highly sensitive nervous system will give great warnings of small approaching evils; it quickly sounds the alarm, and a violent rigor, with chattering teeth and sinking pulse, are sometimes the heralds of a mere bilious attack. In the well-poised constitution only is the preliminary depression to be regarded as a fair criterion of the illness which is to follow.

In ordinary cases of spontaneous inflammation, we are not cognizant of any local change corresponding to this general suffering, and during the continuance of this preliminary stage, we often cannot tell what organ is to be the seat of the inflammation. So that we might imagine the constitutional depression to be the prime mover of the disorder, and the local inflammation to be the consequence of it. Such may sometimes be the order of events. More commonly, however, it seems probable that the general prostration is the result of an impression originating in some particular part. Thus, wet feet, or an exposure of some part of the body to a draught, occasion a general feeling of chilliness, which is followed by inflammation in an organ, distant, it may be, from the one where the first impulse to the disorder was given. In case of accident or operation, the constitutional depression or shock, is clearly the result of some particular condition of the injured part communicated to the system. It corresponds in its severity to the extent of the local lesion, and the importance of the injured organ, and gradually gives way to the symptoms of reaction, which, perhaps, pass on into inflammatory fever. Frequently the general depression remains for a short time after the manifestation of the local disease, which then shows itself to be in advance of the constitutional disorder. It is probable that the usual order of sequence of the events of inflammation with fever, are, first, some particular condition of the organ about to be inflamed, corresponding with, and standing in the relation of cause to, the constitutional depression which is the second event in the attack; thirdly, the symptoms of local inflammation are developed, ensuing as a reaction upon the depressed condition of the organ; and, fourthly, the inflammatory fever, which is the reaction from the general depression, increased and modified by the direct effects of the local inflammatory action, and the sympathetic relations of the body in the manner just mentioned. The effects of frost-bite upon a limb, and through it upon the system, are no bad illustration of these remarks, the stage of local depression being here more appreciable than under ordinary circumstances, and the subsequent inflammation, following more clearly as a reaction from it, is seen to be proportionate to it in the severity of its effects.

In what manner the local and general reaction depend upon the local and general depression I cannot tell, though there is very little doubt that they do so. The well-known fact that the latter may be prevented by cutting short the former is sufficient evidence of this. The treatment of ague is conducted upon this principle, the arrest or prevention of the preliminary shiver by warm drinks, or the application of external warmth, being the sure means of curtailing or warding off the subsequent stages of the fit.

As a general rule, the attendant constitutional symptoms bear a certain relation to the extent and severity of the local disease, but they are not always a measure of its danger. They are strongly marked in acute rheumatism, which, so long as it is confined to the joints, is free from danger. They are in greater force when associated with inflammation of serous and

fibrous, than of mucous membranes, and the parenchyma of organs. They are, besides, often modified by the altered function of the organ affected. Thus, in inflammation of the heart or brain, the general fever does not always correspond with the amount of local disturbance, owing to the direct impairment of the great circulatory organ in the one case, and the nervous centre of the other. Or, they may be modified by peculiarity of the patient's constitution or by some previous indisposition, and want of vigour of one or more of the great organs, rendering them unable to respond to the stimulus of the local ailment in the same manner as the others. Peculiarities of this kind, intermitting pulse, convulsions, &c., showing a want of order and of due proportion between the symptoms of inflammatory fever, furnish cause for alarm in no less degree than a more severe train of symptoms, in which the several parts of the body evince a greater equality of enduring power.

In the treatment of acute inflammation with inflammatory fever, we have to deal with a local disease and constitutional disturbance, acting and re-acting on each other, and our efforts are first directed to quell the latter as the most effectual means of checking the former. By far the most powerful remedy at our command is blood-letting, which is, perhaps, of more avail in arresting the disease than all our other resources combined. As a general rule, so long as the inflammation is confined to a part, we are content with the local abstraction of blood by leeches or cupping; but when it has extended to the system, and fever is superadded, it is necessary to resort to venesection. Of the need of this treatment, and the extent to which it should be carried, we form our opinion from a knowledge of the constitution of the patient, the severity of the disease, and the importance as well as the nature of the organ affected. In a case of acute pleurisy or inflammation of the lung, with inflammatory fever, in a strong and robust person, the free use of the lancet is strongly called for. The disease is violent, the organ of vital importance, and the patient strong. A large quantity of blood may be drawn; the relief afforded is often immediate and very decided. The blood coagulates into a small clot, which is tough, buffed, and cupped. When the inflammation is seated in the lining membrane of the lungs, the inflammatory fever is generally less intense; blood-letting must be cautiously employed, for symptoms of prostration are likely to follow, the relief afforded is less decided, and the coagulum of the blood is larger, softer, less buffed and cupped.

It is usually advisable to allow the blood to flow till a decided impression has been produced upon the system, and the indications of approaching faintness, such as acceleration of the pulse, paleness of the face, and the appearance of moisture on the lips and forehead, are the intimations that sufficient impression has been made. Place the patient in a sitting posture, that you may have early warning of the approach of faintness, and close the vein as soon as the symptoms just mentioned show themselves, for the faintness often

increases after the blood has ceased to flow. The quantity of blood which it is desirable to abstract, is such as the patient will bear to lose without fainting, and is often a measure of the severity of the disease, and the necessity of the treatment.

The pulse is the most unerring indication of the existence of that degree of inflammatory fever which requires general bleeding; and the quality of the pulse on which we chiefly rely in deciding this point, is its hardness. You are aware that the pulse is caused by the alternate distension and contraction of the arterial tube, as the wave of blood is driven through it by the force of the left ventricle of the heart. There are, therefore, three elements concerned in its production, each of which impresses its peculiar value upon it as a symptom; these are, the quantity of the blood, the action of the heart, and, thirdly, the tension of the arterial tube. Upon variations in the first of these depend the fulness or emptiness, the plethoric or anæmic condition of the pulse. By the excitement or depression, and other variations, of the second, is caused the rapidity or slowness of the pulse, its regularity and rhythm, or the reverse, while the strength of the heart's action gives it force. Lastly, the soft or hard feel of the pulse varies with the degree of tension of the arterial tube. When this is slight, the dilating artery accommodates itself easily and gently to the advancing wave, and when that has passed, it gradually resumes its former state, whereas a tense rigid condition of the artery gives to the pulse a hard unyielding feel, and renders its vibrations scarcely perceptible to the finger. Under such circumstances, also, a large amount of blood may be drawn before it is missed from the arterial system; in other words, the quantity of blood may be greatly reduced before it will cease to distend the tightly-contracted arterial tubes, or before they will become relaxed, and faintness be perceived.

Faintness is associated with a condition of the pulse directly the opposite of that we have been just considering. It imports an imperfect distension and relaxed condition of vessels, and that the cerebral substance does not receive its proper amount of pressure from the blood contained in them. The faintness produced by venesection in inflammatory fever is an evidence, therefore, that the arterial system is sufficiently relieved, and the earliest indications of its approach should warn us to close the vein, because, as the faintness proceeds, the vessels become more and more relaxed, and the heart's action enfeebled, in consequence of the diminution of the nervous influence by which the excited action of both was maintained. A forcible action of the heart always, and a frequent action generally, accompanies the hard pulse.

After venesection to approaching syncope, the more urgent symptoms of inflammatory fever are generally relieved; the patient, hitherto restless and in pain, falls asleep, the secretions are restored, the skin becomes soft and moist, the urine is more copious, the action of the bowels is easily induced, and the disease, perhaps, is effectually arrested. It is necessary, however, to be aware of the reaction which is likely to follow the depression caused by loss of blood; this reaction is more or less

proportionate to the preceding depression, and is an additional reason for not carrying the depletion beyond the amount required to control the excited condition of the circulatory system. It may often be lessened or prevented by the adoption of antiphlogistic treatment after the bleeding, and the timely abstraction of a small quantity of blood from the inflamed part when it is commencing. It is well to bear in mind that the reaction, dependent in part upon the preceding depression, is not to be regarded and treated as a relapse of the inflammatory fever. General bleeding should not be again resorted to, unless decided hardness be added to the quickened state of the pulse. The reactionary exacerbation of symptoms usually subsides again in a few hours, or yields to milder measures, and the benefit of the first bleeding is then more completely apparent.

Much has been written about the period of an inflammatory attack at which bleeding is most beneficial, and the comparative advantages of early bleeding. I think the common sense view, that so decided a measure, attended, as it unquestionably is, with some danger to the patient, should not be resorted to till symptoms have arisen which require its employment, will generally prove to be correct. The practice of bleeding to *prevent inflammation*,—that is to say of bleeding persons who have been exposed to the exciting causes of inflammation, such as severe injuries, operations, &c., must, on the whole, be injurious, though there may be exceptional cases rendering such treatment advisable. Bleeding before operations, except where inflammation already exists, as in some cases of strangulated hernia, and other treatment which lowers the vital powers of the patient, only renders him more amenable to the shock of the operation, and the inflammatory reaction which is likely to follow. Patients who are in the weakest state, or who have lost the most blood during operations, are the least likely to recover; in them we have most reason to apprehend the occurrence of those dangerous inflammations in different parts of the body, followed by suppuration or "purulent deposits," as they are sometimes called.

During the preliminary stage of depression, depletion is, of course, out of the question; but when the symptoms of inflammatory fever have fairly commenced, and the pulse has become hard, it is absurd to wait for their further development. By the timely abstraction of blood when the symptoms of inflammation are setting in, we may often cut short the disease, and at once relieve the patient. The advantage of decided measures at this particular period of the attack, you have lately seen exemplified in two cases of commencing inflammation of the brain, consequent on injury of the head, in both of which the symptoms were at once arrested in an early stage by moderate bleeding, followed by antiphlogistic regimen, and did not again return.

A few years ago, no doubt, a vast amount of evil was done by the extravagant use of the lancet; but lately, as a natural consequence of excess in its employment, the tide of opinion has set so strongly against this weapon, that I think disease gains some advantage from the timidity of modern practitioners in

resorting to it. The right time for bleeding is often allowed to pass, and the inflammation, unchecked by milder measures, runs on to a stage when its destructive effects are rather aggravated by depletion, which, employed at an earlier period, might have prevented their occurrence.

In addition to the diminution and dilution of the general mass of the blood caused by bleeding, the red particles are disproportionately decreased, and the quantity of fibrin is also diminished, secondarily, and in less degree. It is probable that the good effects resulting from depletion in inflammation are due, not so much to a change in the relative proportions of the constituents of the blood, as to a direct effect in reducing the force of the disease by withdrawing the pabulum of the process, the fuel with which the flame is fed, and to the lowering of those vital energies of the blood and of the patient, in the exaltation and aberration of which the morbid phenomena consist.

When the accompanying fever is slight or has been checked by general depletion, the abstraction of blood by leeches and cupping from the neighbourhood of the inflamed part, is a very effectual means of combating the local disease. Leeches are suited to the greater number of the cases which fall under the care of the surgeon, because they are attended with less violence than cupping. The pain and inconvenience connected with the employment of cupping-glasses and the scarificator, often do more harm to an inflamed and tender part, (the knee-joint for instance,) than the loss of blood does good. In the case of inflamed hip, the joint being more deeply seated, this objection does not apply; and the sudden abstraction of a few ounces of blood from behind the great trochanter is, on the whole, more serviceable in an acute inflammation of this joint, than the gradual loss of the same quantity by leeches.

No doubt one of the advantages of leeches, rendering them especially suited to relieve chronic inflammatory affections, is the slow manner in which the blood is withdrawn, producing a gradual effect upon the inflamed part, and followed, therefore, by less reaction. For the same reason the bleeding from the leech-bites should be encouraged by the application of warm moist flannels, which is, perhaps, the method of fomentation least fatiguing to the patient, and it is sometimes desirable to maintain a continuous oozing by a relay of leeches, when the bleeding caused by the first batch begins to cease.

Whether leeches or cupping be employed, there is no doubt that the benefit is most apparent when the blood is drawn from the integuments covering the inflamed part. Some sympathetic connection probably exists between the skin and the organ situated beneath it, whereby the impression made upon the one is communicated to the other. But it is not generally advisable either to cup or apply leeches to the inflamed part itself; the irritation occasioned by leech-bites in inflamed skin generally increases the disorder, and may give rise to troublesome sores, or even to mortification. Inflammation of subcutaneous absorbent glands, in which the skin is implicated, is commonly aggravated

by the application of leeches, unless they be placed in the circumference of the inflamed part; and in epididymitis, accompanied as it often is by considerable inflammation of the integuments of the scrotum, the good effects of leeches are most fully obtained by placing them over the cord where it is rising to enter the abdominal ring. I believe also that in inflammation of the os uteri more benefit is derived from the leeches applied to the integuments about the anus than to the organ itself. In chronic inflammation of the absorbent glands and epididymis, where the integuments are but little or not at all involved, the leeches should be applied immediately over the part affected. In inflammation of the eye they should be placed upon the temple, and not, under any ordinary circumstances, upon the tender skin of the eyelids.

The number of leeches should be proportionate to the severity of the disease. In acute inflammation of the knee, one or two dozen are required to arrest the attack, if possible, by a sudden and decided impression. In a chronic inflammation of the lobules of the breast, or of the epididymis, with induration, the purpose will be best attained by a less decided but more continuous or repeated impression, and the application of two or three leeches every three or four days, is, in such cases, most beneficial.

The good effects of mercury are most apparent in the inflammations of vigorous persons, and in those more particularly which are attended with the formation of new products, causing induration of textures, and adhesions of parts which ought to be free, such as inflammations of serous membranes and the iris; whereas, in inflammations of a low type, in those which are combined with symptoms of typhoid character, in old people, and in persons of delicate, irritable, nervous constitution, in inflammations of mucous membranes, and in other cases where the effects of the inflammation are displayed in destroying the tissues, and in promoting ulceration and mortification, rather than by effusions of lymph, the administration of mercury to such an extent as to produce its peculiar influence on the constitution is likely to be injurious. You will seldom err in following the rule of giving mercury to persons of strong constitution, when the inflammation is seated in a texture where we know it is likely to be followed by effusions of lymph, and of withholding or exhibiting it very cautiously in weak and old people, or whenever ulceration and mortification are likely to ensue.

The effects of mercury are influenced to a certain degree by the character of the inflammation, thus certain of the syphilitic affections, though attended with ulceration, are benefitted by mercury; but whatever may be the character of the inflammation, provided it be seated in a texture where effusions of lymph are likely to take place, the use of the mineral is almost always indicated. This is peculiarly true of iritis, which, whether owing to syphilis, gout, or any other cause, yields to the influence of mercury more surely than to any other plan of treatment.

An irritable and excited condition of the nerves of the part affected, and of the nervous system, constitutes

one of the features of inflammation, so that we naturally look for benefit from medicines which are known to exert a sedative influence. Opium has long been much used in the treatment of inflammation, and confidence in it as an auxiliary to other measures, is felt by surgeons of the present day, perhaps, to a greater extent than by their predecessors. It is well combined with mercury, assisting that medicine, and at the same time producing its own effect. It is a most serviceable adjunct to venesection, quieting the nervous system when the circulatory forces have been reduced by bleeding, and controlling the reaction which is likely to follow after the loss of blood. It is especially indicated when the symptoms of irritability and restlessness predominate, and in delicate asthenic persons, where blood-letting and other active treatment are forbidden. It is further indicated when the part affected, from its particular position or function, is kept in continual action by the irritation caused by inflammation. Thus a dose of opium allays the frequent and urgent desire to void the urine which accompanies inflammation of the bladder, and which necessarily aggravates the disorder.

The administration of opium is often attended with much relief when inflammation is passing on to ulceration and mortification, in cases of phagedenic ulceration of the throat in debilitated persons, and in senile gangrene, and in a great number of painful inflammatory affections, attended with restlessness and want of sleep.

I will here make three remarks by way of caution to you in the administration of opium. 1st. Beware of giving it when the sensibilities of the nervous centres are beginning to fail, in consequence of imperfect aeration of the blood, congestion of the brain, or other cause; under such circumstances, it will be most likely to hasten the patient's death. 2ndly. You should not forget that it is a most alluring medicine to the patient, who, having learnt its agreeable, sedative, and comforting influence under your direction, will have great difficulty in resisting the temptation to continue it. A great number of confirmed opium-eaters have contracted the habit in consequence of the drug having been prescribed to them as a remedy for the cure of some disease. And, 3rdly, the sensibilities of the patient seem to be increased, and his ability to endure pain lessened, by its employment. I have been struck by this effect of opium in several cases which have fallen under my notice, and it has made me unwilling to commence its use unless there be some clear prospect of curative influence on the disease. The sufferings of a patient with stone are, I believe, in the long run, aggravated by it, and in malignant diseases we resort to it as the least of two evils, conscious that we can continue to procure relief from pain only by progressively increasing the dose.

THE

CONTAGION OF ASIATIC CHOLERA.*

By E. O. SPOONER, Esq., Blandford.

I have already alluded to the variola ovina, as offering an example of the progress of a disease notoriously contagious, and presenting analogies which it will be desirable to examine, in elucidation of the cholera importation. Flocks of sheep do not migrate and commingle to the same extent as human beings; contagions, therefore, do not spread among neighbouring flocks with the same rapidity as cholera marches from town to town. An Act of Parliament was passed last session, 11 and 12 Vict., cap. 105 and 107, for prohibiting the further importation of cattle affected with this disease. Inspectors of foreign cattle have been appointed at our chief ports, and these animals are now subject to quarantine. The diseased sheep are required to be "seized and destroyed," with any pens, hurdles, litter, hay, straw, or other articles likely to have been infected." In 1837, Mr. Youatt, an able writer on the diseases of cattle, declared that no such disease was known in England, and he described it on the authority of the French veterinary professors, by whom it was called "*Clavelée*." It had been noticed by them as early as 1747. The free importation of sheep under the new tariff brought it into this island; *a restricted commerce kept it out of this country for a hundred years*, during which time it had manifested itself pretty generally on the continent of Europe, and had often thinned the flocks of France. For a long time in the Hamburg market a separate place had been appointed for the contaminated sheep. Inoculation of the sheep has been employed in France very successfully, with an average mortality of one in four hundred. *No foreign sheep are now to be introduced without a warrant from a veterinary surgeon.* Had such precautions been observed on the first adoption of free importations, many of our agriculturists would have been preserved from immense losses which they have already sustained from this contagious epizootic. The disease, however, is now introduced *into many of the counties of England*, and it spreads into places where *communication cannot be fully traced, the atmosphere appearing to be the vehicle of infection.* It has been well observed, that if the quarantine laws are to be abolished, let the experiment be tried *in corpore vili*: we have it seems reversed the experiment. Crews sick with the cholera have been allowed free pratique, while the most stringent measures have passed the legislature to enforce quarantine on diseased cattle! We do not find our non-contagionist doctors have tried their hands upon this epizootic, or, perhaps, we should hear that contagion was an exploded doctrine, only fit for the dark ages,—that the pestilence came on the

wings of the wind, and crossed the Channel, nobody knew how,—that although it was never known in England till the new tariff, it was entirely owing to a neglect of sanitary regulations in our sheep-folds! Very learned discussions, no doubt, would clearly prove, that though it might have been first noticed in vessels arriving in our ports from abroad, it was entirely to be attributed to its particular “*penchant* for the mouths of rivers;” that it had a peculiar knack of jumping over one place and settling in another; and that after a few cases had occurred in a British port, it was quite useless to keep up quarantine regulations, which had been found ineffective on the Continent! Now, the absurdity of these positions are patent to every understanding, when applied to the variola ovina. If the cholera be a contagious disease, which every day’s experience gives us more and more reason to believe, the fallacies of our Board of Health and our Sanitary Commissioners must strike the common sense of the community. *The removal of all quarantine within a few days after the first cases of cholera had occurred at Hull was soon succeeded by numerous cases in the ports of Leith and London.*

If it be objected that inferences drawn from epizootic diseases are less decisive than those derived from epidemics, let us examine the records of the small-pox in man. In the metropolis we have already alluded to the evidence of Dr. Gregory, but in places of less population we can easily track its steps. About four months ago, a case of small-pox, which had been treated in St. George’s Hospital, was sent, after recovery, into the country. It had been a severe case of the confluent form, but the whole surface of the body had been covered, and a new skin had been formed. The young patient had been convalescent a fortnight; his clothes were supposed to have been purified, and the physician who attended assured him that it was quite safe for him to return to his family in the country. No case of small-pox had occurred in the parish of Spetisbury for fifteen years. Within a week after his arrival his elder brother sickened of the small-pox; it was severe and confluent, but he recovered. His younger brother took the disease a fortnight afterwards; it was distinct and mild. All three had been previously vaccinated. By strict measures of quarantine, and by vaccinating the children of the village, and re-vaccinating the adults who lived near, we succeeded in arresting the disease. Had these been cases of cholera instead of small-pox, it might, perhaps, have been denied that the St. George’s case produced the other two cases; it might have been said separation of the sick for six weeks, which we adopted for the rest of the community, was an unnecessary measure, and that the disease being very capricious, died out of its own accord.

Now, I have a very strong objection to the use of such an unphilosophical word as “*capricious*,”

as belonging to any disease. It is always in the mouths of the non-contagionists, because they cannot account for many of the phenomena of cholera without supposing the malady capricious, as if the poison of contagions followed any other than natural and regular laws. The caprice only exists in the understanding of those who use the term. The pathological laws of cholera are as definite as those of the Medes and Persians. It is sometimes called, too, a “mysterious disease,” and we confess that it must be a very great mystery to all those who deny the existence of contagion. But, the mystery to me is, that after so much has been written, and so much observed, people should yet imagine there is any mystery at all about it. Why, if the cholera is a mystery, the plague is a mystery, the small-pox a mystery. We shall never know under what peculiar organic or inorganic conditions the poison of small-pox originated, though mankind have studied it for the last eight hundred years, but we know some of its laws which are of great utility in preserving us from its ravages, and the most important laws upon which all our prophylactic powers have been based are its laws of contagion.

The malignant scarlet fever in all probability was the plague of Athens, described by Thucydides. The records of early pestilences are, however, very meagre and imperfect. The small-pox and measles were no doubt much more formidable in the invasions of new countries, as modern history has taught us. The American Indian tribes have sometimes perished by thousands, when the epidemics of civilized nations have introduced among them the contagious poison of various diseases of the civilized world. “Yet, (says Dr. Odier,) at some periods small-pox and plague carry off hundreds: at others, children whom we inoculated, have gone out every day, even after the eruption had broken out;—they have been in the streets and public walks;—they have communicated freely with other children susceptible of the infection, and not only the small-pox did not spread, but there did not occur, to my knowledge, any distinct instance of communication of the disease from one individual to another, in the streets or promenades.” *Yet the small-pox spreads only by contagion.* Dr. Haygarth, in his “Enquiry how to Prevent the Small-pox,” has given us an accurate account of this epidemic in Chester, in 1777:—“At the beginning,” says he, “two or three families were seized, not immediate neighbours, but in the same quarter of the town. Afterwards, the poor children in several parts of the town were attacked at a considerable distance—in some places half a mile—from each other.” Yet many portions of all the large streets were not infected in November, (the epidemic began in May,) but so late as December and January the distemper returned to attack many who had escaped when it was in their neighbourhood some months before. In the middle of the city, in one street,

(King-street,) of twenty-four who never had passed through the distemper, only two, both in the same house, were attacked. During the summer and autumn of 1777, while this epidemic was general in Chester, many of the surrounding villages, (as Christleton, Barrow, Tarvin, &c., and some larger towns,—as Nantwich, Neston, &c.,) were visited by the small-pox in one or more families; yet *the distemper did not spread generally through any of these towns.*" We ask, have not such irregularities occurred in cholera? Do they prove the non-infectious character of cholera, when the same circumstances attend such a notoriously infectious disease as small-pox? Positive facts of contagion are not to be laid aside for negative facts, which disturbing causes as clearly explain as they do the perturbations of Uranus. Though these puzzled the astronomers for some time, no one was bold enough to attribute them to the non-existence of the laws of gravitation. In the *Provincial Journal* of November 15th, I have related the circumstances attending the invasion of cholera in the village of Bere Regis in this county, in 1832. One solitary case from London, where cholera was raging, terminated fatally. Within a month, twelve other cases of Asiatic cholera occurred, six of which were fatal. Not a single town or village around Bere presented a case before or since that period. Such well-marked and definite instances are not to be explained away.

We will add another signal instance of contagion during the present epidemic:—A boatman on the canal, with his wife and family, returned a few weeks ago from London, where cholera was of frequent occurrence on the river. They were seized with illness on the way. One child died on the passage, and they were all very ill when they arrived at the village of Offchurch. They were put into a room occupied by other persons. No suspicion of cholera existed. After the death of the woman and two children it was suspected that they had been poisoned and an inquest was held. The truth now became manifest, and eight other cases occurred, six of which proved fatal. Within the last fortnight four fresh cases have occurred. Now, Offchurch is a village in the very centre of England; no case of cholera had occurred in its neighbourhood until the fatal boat from London introduced it. Had such facts occurred with regard to small-pox, not the slightest doubt of contagion would have existed in any mind. The style of reasoning must be very far-fetched which refuses a parity of logic for the Asiatic cholera. We deem these instances glaring and decisive, and little short of the "*Experimentum crucis*" of Lord Bacon.

The contagion of hooping-cough is one in which the atmosphere forms the vehicle of morbid germs, but in which no eruption like the *exanthemata* exists. Within the last six months it has fallen to my lot to trace its invasion of a village in Dorsetshire, owing to the

importation of a single case from Portsmouth, and during the same period a connection of a patient of mine has carried the disease to the island of Tenriffe, where the disease *never appeared before*. Soon after the introduction of the first patient, who had the disease on board-ship, (having caught it of a sister at school in the west of England,) the whole island became the subject of this contagious epidemic. It is quite erroneous to call this disease, or scarlatina, or measles, infantile diseases; they are diseases to which all adult mankind are liable, as is clearly proved when *they attack a new community*. The adults who have gone through the disease in countries where these epidemics have long existed are contagion-proof; the children are generally the only parties left susceptible of the poison.

This should teach us a lesson with regard to cholera. If possible, those only should be employed with the sick as nurses, who have gone through the disease previously; they are generally contagion-proof.

The February number of the *Journal of Public Health*, alludes in terms of high and deserved eulogium to the efforts of the Medical Staff of the army and navy in improving the health of the soldiers and sailors, by wise sanitary regulations. We think the praise is well deserved, but on the subject of contagion there is much still to be done, as will suggest itself to anybody who peruses the following short statement of facts, which have lately come to my knowledge. Last year six hundred men, principally fresh recruits from the north of England, were ordered to Portsmouth to embark on board a transport ship for Malta, to relieve our Indian regiments. They arrived in London, but instead of being located in barracks, they were distributed by their billets into various lodgings about town. The public houses provide these temporary accommodations instead of receiving them as inmates. On the following morning the regimental roll was read over at the station; every man, to his credit, responded to the call. They went by the train to Portsmouth, and embarked the same day. Before their arrival at Malta, the small-pox and typhus fever, which a few of the men caught in one night's sojourn in London, broke out, and they were obliged to go into quarantine at Malta, where two hundred lay sick, of which number eighty men died. The commanding officer was obliged to return invalided, and two hundred men were put *hors de combat* from this one night's exposure to the infection of indiscriminate lodgings found for them in London. At their depôt in Lancashire, the men were perfectly healthy. The ship was a large and roomy one, affording the usual accommodations; and contagion alone, which might have been guarded against by the men going into healthy barracks in town, was the *sole efficient cause of this dreadful mortality*, which exceeded that of the Pauper Asylum at Tooting. We have not heard that any verdict of manslaughter has yet been

recorded against any of the Government authorities, whose want of foresight led to this sad catastrophe! Mr. Grainger would have been puzzled to find Tooting drains and Tooting starvation to account for the mortality on board this Government ship!

In an article of mine, published in the *Provincial Journal* of November 15th, 1848, it was observed:—"The mortality from yellow fever on board the *Eclair*, in one of our own roadsteads, clearly proves that the scourge of Africa can propagate itself in the temperate climate of Britain; and while we keep up at an enormous expense of human life and treasure a blockading squadron along the African coast, in the vain hope of exterminating slavery by such means, it is very possible, at some future period, the fever of the Niger may locate itself for a while on the banks of the Thames." The last mail from the West India islands announces, in corroboration of my opinion of the danger arising from the African squadron if quarantine be abolished, the recent re-importation into Barbadoes, by a vessel from Africa, of this pestilential yellow fever, as an alarming fact. The African fever has been actually imported into this island by the very channel pointed out, and sixteen officers appear to have already fallen victims to the plague. We have not yet an accurate report of the number of the men belonging to British regiments who have been attacked and perished, but the quarantine of the *Eclair* at the Mother Bank was ridiculed by the non-contagionists, and in Barbadoes their free pratique system had its full fling, and has produced its frightful fruits. In the midst of the dying and the dead, we are told that the work of Sir William Pym, which demonstrated so conclusively the contagion of yellow fever, is read with terror and dismay, and the speculative dogmas of the non-contagionists are scattered to the winds by the force of facts patent to every understanding. No doubt we shall hear the old story of drains and swamps, and cess-pools, and dust will be thrown in the eyes of the community to prove that yellow fever has been generated in a locality where so little has been latterly known of it, that the medical officers seem to have mistaken entirely the character of the new disease, which baffled all their efforts. No isolation of the sick, no quarantine regulations, seem to have been adopted to arrest the first inroads of the invader, and the penalty of ignorance has been paid to teach (we hope,) the non-contagionists another lesson, which Sir William Pym has had great difficulty in enforcing on the authorities at home. We have no doubt the next news from the West Indies will bring us the mournful intelligence of the extension of this contagious disease, which committed such ravages in the last century that in some places the living could not bury the dead; yet Barbadoes is one of the healthiest of the West India islands.

We have been told on high authority that cholera invariably followed the fever-track; and learned

statistics designated the districts in which we were to expect it. The Registrar of Tooting, however, states that it has always been a healthy locality. Had the measles or scarlet fever broken out in an asylum where fourteen hundred pauper children were crowded together, they could not have more clearly shown their contagious properties than the Asiatic cholera has done. Twelve hours of the contagious emanations of a few cholera patients, are sufficient to infect a whole ward. *The diarrhœa is not the avant-courier, it is the cholera itself; complete separation from the non-infected, and ample space and ventilation should have been adopted on its earliest manifestation.* To suppose the drains of Tooting could have produced the disease, is manifestly absurd, as the inhabitants of the village, who were in the more immediate proximity, were, and are at this time, perfectly free from the malady. The recurrence of cases weeks after the boys had been removed into other localities, and the *fatal cases among the nurses who had never been at Tooting at all*, are direct proofs that *contagion alone was the efficient cause.* When the disease has spent its fatal influence on the more susceptible, it subsides spontaneously; and from Dr. McCann, at Bilston, down to Dr. Sutherland, at Glasgow, great credit is always given to those who are called to act in the last few weeks of a cholera invasion. It reminds us of the Prussian victory at Waterloo.

It is too much the fashion now-a-days to confound all distinctions in classifying diseases. The efficient cause of scarlatina and typhus is, without evidence, assumed to be identical. In earlier times small-pox and measles, and chicken-pox, were thought to be the same malady. Our modern pathologists, who took so much trouble to rectify the errors of ancient diagnosis, are now set aside as drivellers by men who deem yellow-fever, plague, typhus, and continued fever, only types of the same disease. We think the common sense of the profession will repudiate such dogmas, though stamped with the authority of our Board of Health.

We have already alluded to the fact that there are two essentially different diseases in all countries, in India as well as England, though we call one of them English and the other Asiatic cholera. If the specific name of cholera is to remain attached to the pestilential variety, the other should be called *choleroïd*, and the analogies of other diseases suggest the propriety of the distinction. Syphilis has its pseudo-syphilitic mimic in some of the forms of scrofula; there is the grocer's itch, as well as genuine psora. Febrile petechiæ somewhat resembles measles; typhus shades off into some of the forms of uninfected typhoid; variola possesses its varioloid imitations; roseola, with sore-throat, looks very much like scarlatina. We must not, however, confound these essentially different diseases, which require very different treatment, though

they possess some points of similarity. Typhoid, varioloid, scarlatinoid, and choleroïd, are available terms by which we may at the same time designate their differences as well as their resemblances. The *choleroïd* of the summer season of all countries depends on atmospheric or dietetic causes, though it may sometimes assume an epidemic and severe character, as it did in Sydenham's time. But the true pestilential cholera braves even a Russian winter, and so well-known is its grand commercial track, that its visitation is now pretty accurately predicted. *The laws of contagion alone can fully explain its calculable travelling propensities.*

We must, I fear, reasonably expect a general diffusion of the disease in the spring and summer of 1849. Its progress in Scotland has been in a far more rapid and fatal ratio than in 1832. The experience of Tooting should induce our Poor-Law Commissioners to revise all their dietaries, for the general plan sanctioned by them, of porridge and pea-soup feeding three or four times a-week, increases, as we have already shown, the susceptibilities of the pauper population. It is unfair that poor Drouet* should be made the scape-goat of such dietetic errors as have been sanctioned on high authority; and should cholera appear among the inmates of Norwood, I have no doubt we should soon find that the germs of contagion would produce their amply-developed fuel even in that establishment. The abolition of the whole system of farming the poor, should be immediately insisted upon by the Poor-Law Commissioners; and if they abolished at the same time the practice of farming the medical supplies, it would be a great improvement on their system. Physic as well as food should be supplied as they are in our hospitals and dispensaries, and the skill and attention of the medical officers should alone form the basis of their remuneration.

The inconveniences of quarantine laws to a commercial nation like England, holding extensive and rapid communication with all parts of the world, have produced for many years a strong tendency to question their propriety, to obtain a modification of their stringent application, or at once to get rid of them entirely. If it be a fact that these laws have never yet been able to accomplish the object for which they were designed,—that evasions and illicit communications have generally rendered them nugatory,—that the facilities of modern travelling by sea and by land, through the application of the steam engine render them intolerable and less effective than in the earlier states of society, let the Government abolish quarantine with its eyes open, and with a full recognition of the risks we are to run. These questions ought not to weigh one *iota* in the scale when we enter upon the specific inquiry as to the contagiousness of any disease. It may be true

that quarantine laws are now no longer practicable, and yet the plague and the cholera, and the yellow fever, may be infectious. We do not wish to mix up the abolition of the quarantine system with the strictly medical enquiry; the one belongs to the sanitary police of nations, the other involves pure medical truth. Let not, however, the quarantine laws be abolished on a fictitious plea, and under false pretences. If commercial reasons are of sufficient importance to induce a great commercial people to suspend or abrogate these laws, let those reasons rest on their proper basis. We must not bend medical truth to meet the demands of modern society. On the quarantine system I have now no purpose to enter: our present enquiry is limited to the contagion of pestilential cholera; neither do I wish to mix it up with those sanitary improvements which experience has taught to be so essential to the well-being of the community. *Good drainage, ample space, fresh air, a copious supply of pure water, and the removal of all filth and impurity, are valuable and necessary conditions for the healthy physical, and moral development of man; they are sacred projects which I would not for a moment interfere with or oppose; they have an important influence on the health of man, and the course of all diseases, whether contagious or not. These objects, however, must not be advanced at the sacrifice of truth; they must not be obtained surreptitiously by false statements, erroneous inferences, or unfounded perversions of facts; it is too holy a war for such desecrated weapons. A pious fraud may suit the morality of the mediæval period: it is not justifiable in the nineteenth century.*

To sum up, then, the results of these enquiries, we are driven to the following conclusions:—That the cholera is a contagious disease;—that the morbid germ has a period of incubation, varying from three days to a fortnight;—that the milder diarrhœa which, *pari passu*, accompanies the severe form of cholera, is a variety of the same essential disease;—that the emanations from the bodies of the affected, whether in the stage of diarrhœa, collapse, or consecutive fever, are productive of the genuine Asiatic cholera;—that the arrest of diarrhœa, though it does not always prevent cases from running into collapse, is of the utmost importance in mitigating the severity of the disease; and should be considered as the first stage of cholera, to be met by the most prompt medical interference; and careful watching;—that the susceptibility of receiving the disease, in the severest form, is very much lessened by regular, solid, and wholesome diet, partaking in a suitable proportion of animal food, and moderation in the use of stimulants;—that the contamination of fæcal evacuations being the most fertile source of the disease, demands the most cleanly sanitary arrangements; (the exuvie of the skin in small-pox and scarlatina, produce those special diseases alone, as the-

* Since this article was in type, we learn that Mr. Drouet is seriously ill; the report of his death is contradicted.

exuvæ of the mucous membrane produce the special disease of Asiatic cholera; the ordinary results of common vegetable or animal putrefaction being quite of a different character;) that the contagion may be mitigated by the free ventilation of the sick, and the non-concentration of the poison, the purification of the clothing, bedding, and utensils of the affected, should be carefully enjoined;—that its introduction by tramps and vagrants has already, in numerous instances, propagated the disease;—that its invasion of Belfast, New York, New Orleans, and the Texas, in a less time than it has taken to reach our western ports, proves its more easy communicability by means of shipping, and its necessarily *contagious properties*.

The English word contact has nothing to do with the meaning of contagion. Contact is, mathematically, impossible; and the contagion of scarlet fever, whooping cough, &c., &c., are never connected with the idea of physical touch or contact. Neither has the term been used with such restrictions by any medical writer of the contagionist party, or by the public, or by the Legislature. Even Virgil himself does not refer to actual contact when he says—“*Nec mula VICINI pecoris contagia ludent.*” Vicinity is quite near enough, without actual touch. Those who use contagion only in the sense of contact, must be narrow-minded classics, for no fair rules of criticism can justify the exclusive meaning which they would attach to the term contagion.

The history of “Asiatic Cholera” now reaches a period of thirty-two years. *We have no record of any epidemic which could continue in existence in successive years over the various climates of the globe for so long a period, without the ever-living and active principle of contagion as its efficient cause.* No atmospheric cause could have continued in existence so permanently and unchangeably as to produce the same identical disease in all the countries it has visited. Even now many insular situations have been left entirely unvisited. No cause of telluric or magnetic origin could have given birth to such a roving pestilence. We are driven, *par voie d'exclusion*, to the one cause of contagion, and till that is generally acknowledged and fairly met, we are like sailors navigating without a compass. Boards of Health are, indeed, truly enough described by Lord Carlisle, as only Boards of Works, and those works are of a very questionable and blind description. Their first fundamental principle of non-contagion is erroneous; no wonder they flounder on as the registrars of a mortality far greater than their predecessors. The philosophical historian, Gibbon, takes the same view of contagion as the poet Virgil. The graphic description which he gives of the plague in the time of Justinian may be quoted as a beacon for modern times. “Contagion is the inseparable symptom of the plague, which, by mutual respiration, is transfused from the infected persons to the lungs of those who

approach them. While philosophers believe and tremble, it is singular that the existence of a real danger should have been denied by a people most prone to vain and imaginary terrors; yet the fellow-citizens of Procopius were satisfied by *some short and partial experience*, that the infection could not be gained by the closet conversation, and this *persuasion might support the assiduity of friends or physicians* in the care of the sick, whom *inhuman* prudence would have condemned to solitude and despair. But the *fatal security*, like the predestination of the Turks, must have *aided the progress of the contagion*, and those *salutary precautions* to which Europe is indebted for her safety were unknown to the government of Justinian. No restraints were imposed on the free and frequent intercourse of the Roman provinces; from Persia to France the nations were mingled and infected by wars and emigrations, and the pestilential odour which lurks in a bale of cotton was imported by the abuse of trade into the most distant regions. The mode of its propagation is explained by the remark of Procopius himself, that *it always spread from the sea-coast to the inland country*; the most sequestered islands and mountains were successively visited; the places which had escaped the fury of its passage were alone exposed to the contagion of the ensuing year. The winds might diffuse the subtle venom, but unless the atmosphere be previously disposed for its reception, the plague would soon expire in the cold and temperate climates of the earth. Such was the universal corruption of the air, that the pestilence which burst forth in the fifteenth year of Justinian, *was not checked or alleviated by any difference of the seasons.* In time its first malignancy was abated and dispersed: the disease alternately languished and revived; but it was not till the end of a calamitous period of fifty-two years that mankind recovered their health or the air resumed its pure and salubrious quality. No facts have been preserved to sustain an account or even a conjecture of the numbers that perished in this extraordinary mortality. I only find that in three months five, and at length ten thousand persons perished each day at Constantinople,—that many cities of the East were left vacant, and that in several districts in Italy, the harvest and the vintage were left withered on the ground.”

In conclusion, then, I would seriously advise the lay-members of our Board of Health, to associate with their body some of those members of the medical profession who recognize the principle of contagion as the efficient cause of cholera. Fundamental errors have been already committed, as the statistics of the progress of cholera during the last four months clearly prove. Let it not be recorded against them at the end of the year, that the ultimate mortality has exceeded by one-fourth that of the last invasion. Sanitary laws are better understood than they were in 1832. The

removal of the potato as a general article of food has thrown our population upon the healthier cereals for their sustenance; and the resources of medicine have been replenished with new agents available to meet the evil, while the general recognition of the disease in its early and premonitory symptoms, offers a fairer opportunity for the employment of those resources which are not only within our reach, but are proved to be so efficient in the first stage. All these circumstances combine to render our defences against the foe more definite and more complete. The contagious principle of the epidemic being authoritatively denied by our Board of Health, must influence the practice of a large portion of the misguided community, and the means of arresting and destroying that contagion, cannot be enforced by men who "discredit the once-prevalent opinion, that the cholera is in itself contagious." Here is the weak point of our citadel of defence;—here is the Trojan horse which lets in the armed enemy into our besieged towns. The confidence of the profession is already shaken in our Board of Health, and should a far more fearful mortality await us, a verdict of "manslaughter" may at some future period be recorded against a body who have failed in pointing out the first fundamental law of a disease, which the last Board of Health, under the presidency of Sir Henry Hallford, did not fail to recognize and act upon.

ON OLEAGINOUS ALIMENTS IN TUBERCULAR PHTHISIS.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

As one of the readers of your valuable Journal, and a sincere admirer of the intellect and research displayed by the talented authors of papers contained there, and in the "Transactions of the Provincial Medical and Surgical Association," I take the liberty to offer a few remarks on the concluding portion of Dr. Shearman's elaborate paper "On the Treatment of some of the Principal Diseases of the Chest," and published in the last part of the "Transactions." This I do from no desire to depreciate the merits of that justly prized essay, but solely for the sake of eliciting opinion upon the subject.

At page 42, Dr. Shearman states, that in the treatment of phthisis pulmonalis, "the imperfect nutrition will be best overcome by an easily digestible and nutritious diet; milk substances abounding in *oleaginous*, rather than *albuminous* principles," &c. &c. The boasted good effects of naphtha, he says, are attributable to its powers of allaying the irritability of the stomach, and thus enabling the patient to take nourishment. In following the second indication, cod-liver oil rectified is a most valuable remedy. Again, at page 44, he says,—“In attending to the second indication, those

aliments should be *avoided* which tend to increase the supply of *hydro-carbon* to the blood, such as animal food abounding with *fat*, alcohol, &c. &c., and the principal meals should be made from lean meat, and other *albuminous* and *fibrinous* articles," &c.; and he further adds, "that phthisical patients who take a large quantity of cod-liver oil almost invariably become stouter under its use; that it is, doubtless, a tonic, and deobstruent, from containing iodine and bromine, and conveys nourishment to the system in such a form as not to excite;" and he asks, "Can it supply *hydro-carbon* to the blood in a better form than other aliments do, so as to require less oxygen to keep up animal heat?" He also states that "cod-liver oil deprived of its stearin possesses a solvent power over the fat of tubercular deposits, and that this is the opinion of Drs. Bennett and Williams."

It occurs to me that there exists a decided contradiction (perhaps it is a misprint,) in the assertions contained in these passages I have quoted; for, first, we employ substances abounding in oleaginous, rather than albuminous, principles, (and here cod-liver oil does not seem out of place;) but, secondly, why avoid aliments which tend to increase the supply of hydro-carbon, such as animal food abounding with fat, if we are still to employ, as an article of aliment or medicine, cod-liver oil, a hydro-carbon, and with a view to furnish this very substance more completely to the blood? Can it be possible that we are directed in the second instance to avoid fat meat, because tubercular matter is here considered to resemble the stearin in its chemical properties, so that olein thus deprived of this principle can meet in the lungs tubercular matter and dissolve it? If so, I think this theory had better be stated plainly by all who entertain it. Does the matter of tubercle then resemble stearin chemically? If so, why give, in the first instance, oleaginous diet, by which, I understand, meats and soups, abounding in fat, with stearin in abundance? Why thus endeavour to make the body fat, why not rather emaciate the subject of our experiment, rather than thus designedly throw obstacles in the way of the solvent action of our remedy; and again, if stearin and tubercle be in any way analogous substances, our proceeding thus should generate tubercles, and all those who live on the fattest food should have most tubercle. I need scarcely say that such is contrary to all facts and experience. Moreover, the advocates of this solvent theory should select, not cod-liver oil, but much thinner oils, and such as are much more free from stearin.

I thought it had been a fact already established by experience, that neither iodine nor bromine, employed in any doses, large or small, seemed to affect remedially the matter of pulmonary tubercle. Can the infinitesimal quantities of these substances contained in cod-liver effect a reverse of this experience? If so, then let the homœopathists rejoice, for theirs will be a triumph indeed. And lastly, we cannot but remember, how confidently it was asserted not long since, that pyro-acetic spirit (a hydro-carbon,) possessed the happy property of dissolving perfectly the matter of tubercle, both as it existed within the body, during life, and when removed after death; but has this not been proved by experience to

have failed most signally to exert any curative power over tubercular disease, and can we feel justified now in attributing to cod-liver oil this curative property, even supposing we could assign to it an equally solvent power, which I have not as yet seen it asserted that it possesses? I admit that we can take much more of the oil which does not injuriously stimulate, but this does not solve the difficulty.

In these strange times on which we have fallen, it may appear philosophical to advocate that an old exploded article of the Pharmacopœia of the ancients, after holding for centuries an honoured reputation with the hydromel, the roasted lungs, and the *liver of the fox*, as recommended by Celsus, for the cure of asthma and dyspnœa, and long since buried in the tomb of all the Capulets, should now be exhumed and offered as a certain cure for phthisis, and sanctioned by the authority of the names of the wisest and best amongst us. That cod-liver oil may be a fluid as easily assimilated as whale or other oils, I can understand; that nutrition of the body may often result from its hygienic employment, I admit; but that the enthusiasm with which it has been lately re-ushered into practice is not based on correct physiological or chemical principles, I fear; and that it is destined to meet, at no very distant period, a sad reverse of its present professional popularity I will not assert, but do most sincerely apprehend, while at the same time it would afford me much pleasure to be able to hope, that in this I should find myself agreeably disappointed.

I have the honour to be, Sir,

Your very obedient servant,

J. CAREY, M.D.

Lyme Regis, January, 1849.

EFFECTS OF CROTON OIL APPLIED TO THE HUMAN HAIR.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

The following case is perhaps more amusing than instructive, but contains one or two points deserving of attention:—

A few weeks since, early in the morning, I was requested to see a young woman who was very ill in the head. On visiting her I found that, among other attractions, she had a very fine head of hair, over which I was given to understand she was very choice, and had taken very great care to preserve it. For this purpose she had used all the known hair-oils and pomades, having no doubt read, or been told by some celebrated tonsor, that a fine head of hair was the first addition to beauty. Believing this, she applied anything in the shape of grease or oil that was recommended, or she could lay her hands on. Having gone to a new apartment, she found in a cupboard where she disrobed, a very little bottle of oil. Being so small she thought it must be very valuable, and as such, would be a very nice thing for her hair, and she dressed her hair with it at night, and retired to bed. When she awoke up in the

morning, to her great astonishment, she found that she had, by the application of this newly discovered oil, enlarged her head to an enormous size, and what added much to her annoyance was, that her eyelids were so much puffed up, as to be incapable of performing their office, so that she could not see the wonderful effects of the contents of the little bottle she had found, and therefore could have no conception of the transfiguration it had caused. It was for the effects thus produced that my professional assistance was required. She herself thought they arose from what she had used about her hair on going to bed. I requested to see the oil she had been using. The bottle was produced, which at once explained the cause of all the mischief that had been done. It was the usual sized bottle of the *Oleum Tiglii*, or croton oil, which I think contains about a drachm. The whole had not been used. I have never seen it used externally, but I believe if it is rubbed on the skin it generally causes an eruption of a pustular kind. In this case there was nothing of the sort; there was very great constitutional derangement, which I think was brought on more from the fright than from the mischief that had been done; she complained of great heat and pain about the head and the scalp, which was unusually swollen, and gave the sensation of pressing a cushion when the hand was applied to it. There was no appearance of inflammation; the forehead looked more like marble than anything else; the eyelids were rather red, but not like inflammation; still there was great heat over the head. With cold applications and saline purgatives, all the symptoms subsided. In the course of this and the next day my patient was well. The only point that I can see deserving notice in this, which I suppose may be considered as rather a singular case, is the extraordinary and rapidly absorbing power of the human hair, as well as the potency of the *Oleum Tiglii* as an irritant. I should say that there were not more than twenty drops of the croton oil used, and not one drop of it could have touched the scalp.

I am Sir, your obedient servant,

Bath, December 26, 1848.

GEO. KING.

NEW ANÆSTHETICS.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

Though my paper "On Anæsthesia, and the Agents by which it may be produced," will appear in the forthcoming part of the next volume of the *Transactions of the Provincial Medical and Surgical Association*, now in the press, yet as some little time will necessarily elapse before it can be published, it may not be improper nor without interest, to state, that amongst the many substances upon which I have experimented, there are two which are most worthy of attention, as of easy practical application.

The one, which was amongst the earliest I tried, is common coal gas. It is a safe, manageable, and effective anæsthetic, and very cheap as everybody knows; though

the smell is at first unpleasant, it is inhaled without difficulty or repugnance.

The second is a substance which I have more recently discovered, and if my anticipations be well founded, it will be found to be the best agent yet mentioned, and will, I think, supersede those now employed.

I believe it to be possessed of all the good properties of chloroform, and in a great degree free from those which are objectionable. It is equally pleasant, potent, and speedy in its action. The anæsthesia produced by it may be rendered as profound and as prolonged as may be wished. While a smaller quantity of it than of chloroform, will produce a sufficient degree of insensibility, a larger quantity may be given with impunity. The state of collapse is not so great. The animal may be recovered from a more dead-like condition than where this is induced by chloroform; at the same time the process of recovery is more rapid, and it is unattended by any of those distressing symptoms so often witnessed in animals rallying from a large dose of chloroform.

The substance is the *chloride of olefant gas*, as named in "Fownes' Manual;" the hydrochlorate of *chloride of acetylene*, or *oil of olefant gas*, in the eighth edition of "Turner's Chemistry;" and formerly called *Dutch oil*, or *oil of the Dutch chemists*.

In appearance and smell it is not very dissimilar from chloroform, but in composition it differs most materially. Chloroform being composed of *two* atoms of carbon, *one* of hydrogen, and *three* of chlorine, with a boiling point of 140° , the specific gravity of the liquid being 1.480°, of the vapour 4.2° ; while the chloride of olefant gas is composed of *four* atoms of carbon, *four* of hydrogen, and *one* of chlorine; its boiling point is 180° , the specific gravity of the liquid 1.247°; of the vapour 3.4484° ; constituting differences which are very important, and sufficient, I believe, to explain the facts of its superiority.

I need not here detail any of the experiments upon which this statement is founded, nor the reasons which induced me to make trial of this and many other substances, as they are mentioned at length in the paper to which I have alluded, and which will shortly be in the hands of the members of the Association, my object now being simply to mention the fact.

I am, Sir, yours faithfully,

THOMAS NUNNELEY.

Leeds, Feb. 12, 1849.

CASES FROM PRIVATE PRACTICE.*

By JOHN RICHARD WARDELL, M.D., Edin.

Late President of the Royal Physical and Hunterian Medical Societies, Assistant Pathologist in the Royal Infirmary, Edinburgh, &c. &c.

CASE X.

SCORBUTUS.

T. H., aged 47, a broom-manufacturer, looks pale and emaciated, volume of flesh much reduced, muscles feel flabby and resistless.

January 8, 1847. States that for some years he has laboured under considerable indigestion, which has been accompanied with some pain in the epigastrium and hypochondria; has consulted several physicians, but without any benefit; during the last two years his diet has almost entirely consisted of stale wheaten bread and tea; says that he cannot digest animal food, and in the period mentioned has never taken any, with perhaps the exception of occasionally eating a very small quantity of mutton; for years has not been able to eat a full meal; a sense of fullness and distension has long been experienced after eating; pains in the head, chiefly near the frontal region, invariably follow taking food. Six months ago the gums, without any assignable cause, gradually became tender, and vascular-looking, this symptom by degrees increasing in intensity until the present time, when they are red and spongy-looking, and constantly bleed; soft food can now only be taken on account of the affection. On the anterior aspect of the right thigh, in September last, (four months ago,) a number of small ecchymosed-looking petechiæ were just observed, varying from the size of a flea-bite to that of a No. IV. shot; these came gradually, disappeared, and were succeeded by others of a like character. The left thigh in the course of a few weeks after assumed the same condition. On the internal aspect of each thigh, a little above the knee, and corresponding with the lower half of the femur, two dark, large, livid patches made their appearance in October last; their colour was of an inky blue, and they seemed as if they had been produced from a violent blow from some even-surfaced body; they have to this date maintained the same characteristics; the one on the left thigh measures about six inches by four; the one on the right is somewhat smaller. The inferior extremities are now œdematous, and the knee cannot be flexed without the feeling of considerable tightness and pain; at the flexures of both, the skin feels tense and indurated; no discolouration; looks rather paler than natural; right knee swelled; bowels often relaxed, fæces being lighter coloured than normal; complains of no tenderness on pressure in hypochondria or epigastrium; says he often experiences some degree of pain over the umbilicus; skin feels dry and harsh; pulse soft, of tolerable volume, 74; tongue paler than natural, and covered with a dirtyish-white coat; lips blanched. Has taken no medicine for some months, with the exception of an occasional dose of the common aperient pills.

Ordered strong concentrated soups, and puddings of sago, rice, &c., (these to be varied as much as possible,) and vegetables. R. Quin. Sulph., gr. v.; Acid. Sulph. Dil., dr. iss.; Tinct. Card. Co., oz. ss.; Infus. Calumb., oz. viiss. Sit mist. cujus capt. oz. ss. ter die in aqua.

18th. Feels in all respects better; soups and puddings have not disagreed with him; gums not so tender, and less spongy, are more naturally contracted, and reported not to have bled so much; eruption less distinct, and the large ecchymosed patches assuming a yellowish tint. Ordered rabbit, fish, or fowl to be taken; also three ounces of port wine daily. Repet. mistura.

February 21st. Much improved in every respect;

* Continued from page 572 of last volume.

countenance more healthy; gums to appearance almost natural. Can take his prescribed diet without being affected with uneasy distension at the stomach. Livid patches fast disappearing, and petechia well nigh gone; less swelling and stiffness in the extremities; bowels moved in natural frequency, and stools improved. Contin. *mistura tonica et vinum rubrum*.

March 29th. Can now eat mutton to satiety, without suffering from pain in the stomach as previously. Takes bottled porter every day to his dinner. Is enabled to go out every day, and walks much better. R. Tinct. Ferri Sesquichlor., dr. j.; Aquæ, oz. vj.; Tinct. Hyosc., dr. ij. Sit mist.; capt. oz. j. ter die.

April 20th. Well, and pursues his occupation.*

(To be continued.)

Hospital Reports.

QUEEN'S HOSPITAL, BIRMINGHAM.

CLINICAL REPORTS OF SURGICAL CASES UNDER THE TREATMENT OF PROFESSOR SANDS COX, F.R.S., SENIOR SURGEON TO THE HOSPITAL.

Reported by PETER HINCKES BIRD, late Resident Medical Officer.

CASE XIV.

ENCEPHALOID TUMOUR ON THE HAND.

Robert Anston, aged 69, labourer, admitted as in-patient on the 26th of October, 1846, under the care of Professor Cox. He states that, twenty-one years ago, he received a pinch on the little finger of the right hand; it mortified, and was consequently amputated at the metacarpophalangeal articulation. It healed slowly, and got quite well. He further states that about three years ago he perceived a smooth circumscribed tumour, referred to the integuments, covering the middle of the fifth metacarpal bone of the right hand; it gradually increased in size until the present time, becoming lobulated, and attended with severe lancinating pain, which was worse at night. About four months ago it ulcerated, and discharged a thin matter. Both his parents are said to have died consumptive. He states that he has always been a hearty man. Can assign no cause for the appearance of the disease.

Present state.—There is a large ulcerated tumour, about the size of an orange, covering the integuments of the fourth and fifth metacarpal bones; the edges of it are elevated, being on the palm of the hand, about an inch and a half high, with two shallow ulcerations on it; the edges are also indurated and irregular;

complains of much sharp, jumping, lancinating pain, which is worse at night; the pain does not extend up the arm; there is no swelling of the axillary glands; countenance sallow and dejected; feels low, but appetite is good; tongue clean; bowels open; sleeps pretty well at night; would sleep very well were it not for the pain in the hand. R. Liq. Opii Sed., m. xl.; Aquæ Menh. Pip., oz. j. Fiat haustus omni nocte.

November 4th. The disease has certainly increased since last report; he cannot bend the ring finger so well; sleeps better after the draught. Cont. haustus.

9th. There is considerable discharge from the ulceration, of an offensive odour; the pain is more severe, but is confined to the spot.

13th. The mass of disease, with the ring finger and remains of the little finger, were removed this morning by Mr. Cox. An incision was made on the palm of the hand, from the ulnar side of the wrist to the interval between the middle and ring fingers, and a similar incision was made on the back of the hand, thus including the whole of the diseased mass; the knife was then carried between the third and fourth metacarpal bones, and the fourth and fifth metacarpal bones were sawn through just above their articulation with the carpus. He bore the operation well. Pulse 90, feeble. One artery required ligature. The edges of the wound were brought together as close as possible, and a fold of damp lint applied.

The fungoid mass entirely surrounded the fifth metacarpal bone, and partly the fourth, and when cut into, it was found to be composed of a soft brain-like substance, intersected by fibrous bands, and was closely adherent to the integuments above and to the periosteum below, none of it being visible below the last-mentioned structure. A portion submitted to microscopic examination was found to contain numerous caudate nucleated cells.

14th. Slept but little last night; pulse quick; tongue furred.

15th. Feels better; slept indifferently last night; bowels open; does not complain of much pain; pulse 98; tongue furred; had rigors this afternoon; bowels confined; complains of thirst. Mist. Salin., oz. j., quartis horis. Extr. Col. Co., (Palmeri,*) gr. x., statim. Morph. Hydrchlor., gr. j., omni nocte.

17th. Slept well last night; bowels open; pulse 90; tongue cleaner; the wound looks sloughy, and discharges a very offensive matter.

19th. Had three rigors to-day; is in no pain; tongue dry and rather brown; bowels open; appetite bad; pulse 120, weak; slept pretty well last night after the morphia; the wound looks very unhealthy, and matter has formed near the head of the ulna. Continue the medicines. To have six ounces of wine; mutton-chop, &c.

20th. Much the same; slept pretty well last night; tongue covered with a brown fur; pulse 102, weak; does not complain of pain; the abscess over the head

* Some weeks subsequent to the last report the patient informed me that during a recent journey which he had taken, he was unavoidably exposed to a heavy rain for some hours, until he was thoroughly drenched—indeed he had not been so wet for fifteen years before, yet he did not take any cold, felt no stiffness, nor was in any respect subsequently affected, shewing that his health was decidedly re-established.

* The extensive use of this preparation at this Hospital enables me to speak of it in the highest terms as a safe, agreeable, and sure purgative. It is prepared by Robinson, Palmer, and Palmer, of this town.

of the ulna has broken, leaving this process of the bone bare; there is considerable inflammation extending from the hand upwards to the arm. Continue medicines.

21st. Sleeps pretty well; tongue clean; pulse 99; the abscess discharges freely, but the inflammation still continues, the redness extending up the arm above the elbow; the wound looks very unhealthy, and the discharge is very fetid.

22nd. Countenance sunken; feels low; pulse 118, weak; an abscess is forming at the base of the thumb. R. Ammon. Sesqui-Carb., scr. j.; Inf. Gent. Co., Oss. Sum. oz. j., ter die. Continue wine. A pint of ale daily.

23rd. Feels very low and dejected; pulse 102, small; slept pretty well last night; bowels open; tongue covered with a brown fur; appetite bad; much discharge of offensive matter from the abscess on the thumb, and from that on the head of the ulna.

24th. Evidently sinking; pulse 106, small, and readily compressed; tongue rather coated and dry; slept indifferently last night; great discharge from the wounds.

25th. Has had many rigors; pulse 108, weak; tongue dry and glazed; appetite lost; countenance pinched.

26th. Much worse; skin cold and clammy; countenance pinched and congested; pulse very weak. He gradually sank, and died at 11 a.m.

Section cadaveris. Body well developed, with a considerable layer of adipose tissue over the abdomen. Brain healthy; all its arterial vessels contained more or less of an atheromatous deposit. Thorax:—There was much fat deposited about the heart; firm adhesions existed between the pleura-costalis and pleura-pulmonalis on the apex of the right lung. The air-cells of the lungs were much distended with air; there was much congestion (probably *post-mortem*), of the posterior surface of the lobes; there were some scattered cretaceous deposit, about the size of a large pea, on the apex of the lung; they were also present, but in less quantity, in the right lung; no secondary deposits of cancer could be detected on the most minute examination; the bronchial mucous membrane was extremely congested, and the bronchi contained much frothy serum. There was a moderate quantity of fat about the root of the heart; right side of the heart healthy; the auriculo-ventricular opening on the left side was partially surrounded with a cartilaginous deposit, and to the inner side of the mitral valve was a considerable deposit of ossific matter, of the size of a kidney-bean; the aortic valves were healthy, with the exception of their being pervious, having several small oval openings in them. Abdomen:—The liver appeared healthy; there was no secondary deposit to be seen in it; its structure was more friable than natural. The right kidney contained in its interior, and at its upper part, a cyst, which would contain a chestnut; it was filled with light-coloured serum. All the other viscera appeared healthy.

From a careful study of the history and appearance of the tumour with which this unfortunate individual was affected, we glean the following facts concerning it:—

1st. That it appeared as a smooth circumscribed tumour, which he referred to the integuments.

2nd. It increased in size with great rapidity, and acquired a lobulated surface, and was attended with severe lancinating pain, which was exacerbated at night.

3rd. The integuments became affected, and after a time gave way, leaving a large ulcer, having ragged, everted, and elevated edges, and discharging a sanious and fetid matter.

From the consideration of the preceding facts, we have no difficulty whatever in arriving at the conclusion that the tumour was malignant, and of the variety termed encephaloid; and this conclusion is much strengthened by the slow, anxious and dejected countenance, the great debility, and the emaciated appearance of the patient, who, it should be borne in mind, is stated to have enjoyed uniform good health, and in whom no disease could be discovered, (save the tumour,) capable of accounting for the constitutional affection.

Having thus ascertained the nature of the tumour, we have now to determine its seat.

From very slight attention to the history and symptoms of the preceding case, it will be evident that it must have originated either in the subcutaneous cellular tissue, or beneath the periosteum. Now, when tumours have their origin beneath a strong fibrous membrane, like the periosteum, they are necessarily of slower growth, more dense and resisting, smoother, more flattened and diffused than when they originate beneath a readily extensible tissue, like that composing the skin; consequently, bearing in mind the description of the tumour which has been given above, it will be seen that the only conclusion to which we could come was, that it originated in the subcutaneous cellular tissue. This conclusion is confirmed by the pathological examination of the diseased mass, which is described as being "composed of a soft brain-like substance, intersected by fibrous bands," and as being "closely adherent to the integuments above, and to the periosteum below, none of it being visible below the last-mentioned structure."

Nothing could be ascertained with certainty respecting the cause of this disease, excepting that it was not hereditary. The patient did not ascribe the origin of the tumour to any blow or other injury of the part.

The treatment of this case may be considered under two heads:—

1st. Was it advisable to recommend the removal of the diseased mass?

We believed the patient to be labouring under a malignant disease, which was, as far as we could ascertain, purely local. The axillary glands were not affected; the lungs and other viscera not obviously diseased; in fact there was no circumstance which militated against the success of an operation, except the advanced age of the patient. While, on the other hand, it was perfectly certain, that if the diseased mass was not removed, it would before long terminate in his death, either from the pain, exhaustion, and sleeplessness consequent on it, or which was equally probable, from the development of secondary cancerous deposits in the viscera; consequently, we could not

doubt the propriety of recommending the patient to submit to the excision of the tumour.

2nd. What operation should be performed?

In considering this question we must bear in mind a principal and important rule in surgery, of saving as much of the hand as possible; it is, indeed, our duty to do so, especially in operations on the right hand. The patient was a labouring man, and, therefore, if part of his hand could have been saved, it would have been of considerable service to him, an attempt was therefore made to preserve as much of the hand as could be done without including any of the diseased mass. The case, however, proceeded unfavourably, for it appears that on the second day after the operation, he had rigors, followed by inflammation, and the formation of abscesses at the head of the ulna and ball of the thumb, and diffuse inflammation of the arm. Had amputation of the fore-arm been performed, the result would have probably been different.

The immediate cause of death depended, no doubt, on the inflammation of the hand, and consequent supuration, occurring in a patient whose vital powers were nearly exhausted.

PROVINCIAL

Medical & Surgical Journal.

WEDNESDAY, FEBRUARY 21, 1849.

The Return of the mortality and state of the public health for the quarter ending December 31st, just issued by the Registrar-General, presents a much more favourable view of the sanitary condition of the country during the period referred to, than could have been expected. The mortality of the quarter, notwithstanding that the malignant cholera had for several weeks made its appearance in the eastern districts, is below the calculated average, and very considerably less than that of the corresponding quarter of the preceding year. The mortality of the districts included in the returns, during the months of October, November, and December, of the year 1847, amounted to 57,925 or 10,068 more than the calculated number; that of the quarter just ended was only 46,124, or 2,571 less than the calculated number, and 11,801 less than in 1847.

The following statement shows the general character of the diseases which proved fatal in London:—

“The deaths in London were 14,725, of which 5137 were caused by diseases of the zymotic class,—namely, 1765 by *scarlatina*, 883 by typhus, 472 by whooping-cough, 126 by erysipelas. *Scarlatina* has been epidemic, and has raged with great violence; it has destroyed more lives than any other disease, and shows no sign of

abatement. The deaths by *scarlatina* in each of the four quarters of 1848, were 615, 816, 1560, and 1765, making 4756 deaths in the aggregate. Small-pox was fatal to 413 persons, chiefly children, who had never been vaccinated. The deaths from small-pox in the autumns of 1841-47, were 75, 108, 114, 571, 106, 42, and 372. Nearly all these deaths arose from the neglect of vaccination, which, under a recent Act of the Legislature, is, nevertheless, gratuitously performed on all applicants, at stations in every district of London. Typhus was fatal to 883 persons. This disease is decreasing, for the deaths in the autumn of 1847 were 1279. The deaths from cholera were 468. The deaths in the autumns of the seven previous years were 3, 13, 14, 5, 11, 15, 12. Consumption was less fatal than usual, only 1450 persons died of that malady. Heart diseases, lung diseases, and liver diseases, were much less fatal, not only than in 1847, when influenza was prevalent, but less fatal than in the autumn of 1846. A hundred and sixty-three mothers died in childbirth; about 17,774 children were born alive; so that one mother died to every 109 children born alive. Of the deaths, 100 were ascribed to *metria*, or childbirth-fever. The mortality from this cause is high, and deserves grave consideration. Thirteen deaths were ascribed directly to intemperance. Thirty-four deaths were referred to *delirium tremens*, generally the result of drinking spirits to excess—a slow but certain suicide. Of the violent deaths, 24 were caused by poison, 31 by wounds, 22 by hanging, 68 by drowning, 63 by burns and scalds, 131 by fractures and contusions.”

The returns from the country districts are generally satisfactory, but both small-pox and scarlet fever appear to have been prevalent, and fatal in many localities.

An elaborate and interesting meteorological report of the quarter is appended by Mr. Glaishen, from which we learn that the changes of the temperature were frequent and great, and that the amount of electricity in the atmosphere was small, “many days together having passed without the instruments at Greenwich being affected.” Thunder storms, however, occurred on several occasions at Whitehaven, and were also observed at different places in the counties of Cumberland, Lancashire, Durham, Devon, Cornwall, Essex, and Kent. These facts are of some interest taken in connection with the season of the year, and the views which have been put forward by certain observers, on the deficient state of the atmospheric electricity during the prevalence of cholera. The report notices the unusually frequent exhibitions of the *aurora borealis*, and in particular the splendid one of November 17th. On all these occasions the magnetic instruments were more or less disturbed.

Proceedings of Societies.

BIRMINGHAM PATHOLOGICAL SOCIETY.

November 2nd, 1848.*

W. C. FREER, Esq., in the chair.

TYPHUS FEVER; DIARRHŒA: ULCERATION OF THE ILEUM AND CÆCUM.

Dr. Fletcher narrated the following cases:—

Harriet Jones, aged 15, a servant, was admitted into the Birmingham General Hospital October 14th, 1848. She had been living in Dale End, had had a cold, and had been feeling unwell for a week past. During the last day or so, diarrhœa had come on every half hour; she had shivering fits, and complained of pains all over the belly. R. Confect. Aromat., dr. ij.; Tinct. Opii, m. xi.; Mist. Cret., oss. M. Sumat, oz. j., quarta quaque hora. Capt. Pulv. Cretæ cum Opio, gr. x., nocte manque.

16th. Diarrhœa has subsided; she feels better; but little abdominal tenderness. Ordered three glasses of wine daily. Rept. Pulv. ad gr. xx., si opus sit. R. Ammon. Sesquicarb., scr. ij.; Mist. Camph., oz. viij. Sum. oz. j. quarta quaque hora.

21st. Typhoid condition has the last day or two been marked. There has been no return of the diarrhœa. This morning she appeared better, and complained of no pain. She died in the after-part of the day.

Post-mortem examination, October 24th.—Thorax:—The pleuræ were free from adhesions; the lungs were generally congested; the lower lobe of the left lung was in the condition of the first stage of pneumonia; the heart healthy. Abdomen:—The liver was pale in colour; the kidneys appeared natural; the spleen was larger than usual; pancreas healthy; towards the lower part of the ileum numerous small typhoid ulcerations existed, these ulcerations were round, small, and sloughy in appearance, elevating and infiltrating the mucous surfaces, around the solitary glands, and the glands of Peyer; in the cæcum the number of these ulcerations was increased, and around there was deposited a considerable quantity of dirty, sloughy, and typhoid matter; no ulcers existed in any other portion of the large intestines.

TYPHUS FEVER: ULCERATIONS OF INTESTINES.

Maria Burgess, aged 15, a servant, was admitted into the Birmingham General Hospital September 20th, 1848, with diarrhœa every half-hour; hot surface; quickened pulse; red dry tongue. Was taken ill three days before with shiverings and headache; lived in service in New John Street, West; previous health good. R. Mist. Cretæ, oz. viij.; Confect. Aromat.; Tinct. Opii, m. xxx. M. Sumat oz. j. post singulas liquidas dejectiones. Two glasses of wine, and beef-tea, daily. Her natural disposition appears to be fretful; this, added to her present condition, renders her more than ordinarily irritable.

21st. R. Ammon. Sesquicarb., scr. ij.; Mist. Camph.,

oz. viij. M. Sumat oz. j. quarta quaque hora. Four glasses of wine daily.

In the course of a few days her febrile symptoms began to diminish, diarrhœa had in a great measure subsided, the skin became less dry, and she showed more placidity of mind, her sleep at night was disturbed.

25th. Having vomited several times during the night the wine was directed to be diminished to two glasses daily, with a continuance of other remedies. Subsequently to this for two days the wine was altogether omitted. She is more fretful, wanders at times, and cries out frequently during the night. Tongue brown and dry, and teeth and lips covered with sordes.

October 5th. The same condition has continued, varied by occasional diarrhœa; she has never complained of, or seemed to suffer pain about, the bowels on pressure. R. Acidi Hydrochlor. Dilut., oz. ss.; Decoct. Cinchon., oz. xij. M. Sumat oz. iss. ter die. Four glasses of wine daily. Delirium during the day and night has been the last few days almost incessant.

7th. Repetantur remedia. Seven glasses of wine daily.

9th. Died.

Dissection twenty-four hours after death. External appearance of body showed emaciation. Head:—The cerebral membranes were slightly congested; substance of the brain natural; slight effusion existed at the base, none in the ventricles. Thorax:—Lungs healthy, presenting evidence of marked static congestion; heart healthy. Abdomen:—Liver somewhat paler than usual; spleen enlarged, congested, and friable; the pancreas appeared healthy in itself, but attached to it, and each about as large as a filbert, were two apparently enlarged glandular substances, containing in their interior a tubercular-looking matter; kidneys slightly congested; the œsophagus at its upper part presented a dusky redness; throughout the entire course of the ileum, cæcum, and large intestine, as far as the sigmoid flexure of the colon, numerous typhoid ulcerations existed, (in the cæcum they were most abundant,) the mucous membrane around the ulcers being infiltrated and sloughy, and covered by a copious deposit of typhoid matter.

LARGE OVARIAN CYST.

Mr. Brindley presented a large ovarian cyst, and gave the following account of the case:—

Mrs. B., aged 43, of short stature, light complexion, married at 22, and bore children rapidly, but usually had good health; dates her disease eleven years back, when after the birth of her sixth child,—a breech-presentation,—her abdomen continued large, and was in the same state after her last confinement, two years subsequently. From this period she slowly increased in size, her general health and activity remaining unimpaired for some years; at length she grew so bulky, that she could no longer attend to her occupation, that of a green grocer. She kept her bed for three years before her death.

In October, 1846, she had become much emaciated, was very feeble, and suffered a good deal from abdominal

* Continued from page 79.

pains. Her great bulk caused her much inconvenience, and bed-sores threatened to form. By the direction of Dr. Fletcher she was then tapped. Previous to the operation she measured, from spine to umbilicus, on the left side, two feet eleven inches; on the right side, two feet seven inches; from ensiform cartilage to umbilicus, two feet; from pubes to umbilicus, one foot six inches. Nine gallons of fluid were removed, and the cyst was nearly emptied. Some small secondary cysts or tumours could now be felt, apparently within the one emptied. The fluid was dingy-yellow, thick and glairy, and contained myriads of small sparkling crystals, which were shown under the microscope to be tables of cholesterine. The density of the fluid was 1020, and in 1000 parts it contained 45 of solid matter. She bore the operation well, and afterwards improved in condition and appearance. Up to this time she had menstruated regularly and profusely, but the catamenia did not afterwards appear. The urine was usually scanty, not more than twenty ounces *per diem*.

She was tapped again in May, 1847, but on this occasion four gallons only of fluid were removed, in consequence of an accident with the canula. In March, 1848, the cyst was punctured, and thirteen gallons were taken away. In September last the abdomen became painfully distended, and its dimensions were considerably larger than on any former occasion. She had become much emaciated, was very feeble, and had an anæmic appearance. On the 12th fifteen gallons of fluid were drawn off by tapping, but on account of her state the cyst was not more than half emptied. Towards the close of the operation several ounces of blood escaped through the canula, and also from the puncture when the canula was withdrawn, proceeding probably from one of the numerous enlarged veins of the abdominal parietes. She rallied imperfectly, and in a few days was attacked with symptoms of inflammation in the cyst. The abdomen filled rapidly, and she became exhausted and emaciated to the last degree, yet lingered to October 14th, when she died. She had been a dispensary patient for years, under the care of Dr. Fletcher, Mr. Blount, Mr. Shaw, and latterly Mr. Hill, as surgeon of the district, took charge of her case.

Autopsy eighteen hours after death.—Extreme emaciation; abdomen of immense size; lower extremities œdematous and there was also infiltration of serum into the subcutaneous and subserous cellular tissue, in the depending parts. The walls presented some other remarkable changes, consequent on the distension of their tissues; their subcutaneous veins were stretched and dilated into large sinuses, the size of the superior longitudinal sinus of the dura mater, feeling like gutters hollowed out in the hard surrounding structure; the muscular substance, forming the parietes, had entirely lost its red fleshy appearance, and in its place was a thick yellowish-white fibrous structure, bearing a close resemblance to the muscular tissue of the uterus. The peritoneal sac was enormously distended; it contained within its true cavity between two and three gallons of a dark thick glairy fluid; this fluid occupied chiefly the upper part of the sac

of the peritoneum, between the large cyst and the diaphragm, also between the posterior part of the cyst and the subjacent viscera. The ovarian cyst (it was the left,) filled the abdominal cavity from the pubes to the ensiform cartilage, imperfectly overhanging the front of the pelvis, and resting on the thighs, and laterally extending much beyond the ilia. It was closely and firmly adherent to the parietal serous membrane, requiring considerable force to separate them, for which, along the linea alba, the scalpel was necessary; it did not adhere to the adjacent viscera, except to the lower edge of the great omentum. The diaphragm, with the liver to which it adhered, was pushed high up into the thorax, together with the heart and lungs. The cyst contained thirteen or fourteen gallons of clear, limpid, reddish-brown fluid, in which an abundance of soft white flakes floated, or had subsided to the bottom. Its walls were thick, firm, consisting of three coats—a peritoneal, a fibrous, of considerable strength and density, and an inner serous membrane, the surface of which was lined with a layer of soft white albuminous matter. Attached to this surface, at its lowest part, were several tufts or projections of soft membranous structure, apparently the remains of small secondary cysts (probably enlarged Graafian vesicles,) which had burst into the general cavity; a few of them were unbroken; one was of the size of a kidney, and consisted of a number of transparent vesicles or cells, filled with clear fluid, and enclosed in a dense membrane; there was also a large pouch, projecting beyond the general outline of the cyst, distinguished from it by the thickness of its walls, and partly separated by a thick fold or duplicature of its coats. A large quantity of lymph, the result of recent inflammation, and a red and congested state of the lining membrane, were also noticed in its lower portion. The uterus measured full four inches in length, and was drawn up as high as the lower lumbar vertebra. This elongation had taken place in its neck, so that the orificium uteri internum occupied a position nearly midway between the os externum and the fundus, thus giving to the uterine cavity the figure of an hour glass. The left Fallopian tube was very large and elongated; its cavity was the size of a common quill, and it lay embedded in the walls of the cyst, covered by peritoneum, under which its outline could be readily traced, as well as that of its fimbriated extremity. The opening into the uterus was wide and trumpet-shaped, the uterine cavity appearing continuous into it. On the opposite side the communication between the uterus and Fallopian tube could not be traced. The right ovary was also diseased; it was a thin semi-transparent vesicular sac, filled with fluid. The liver was small, very soft, and friable; its peritoneal investments and ligaments opaque and thickened, and loosely adherent to the parenchymatous structure. The gall-bladder was full; the bile nearly black, thick, and ropy. Spleen pale and semi-fluid, its serous covering thick and opaque, and covered by a layer of false membrane; pancreas, stomach, and small intestines, healthy. The colon filled with scybala, almost to the cæcum, an obstacle to the free passage of its contents being evidently occasioned by pressure

of the cyst on the gut, as it passed over the brim of the pelvis. The rectum was empty. Kidneys small, pale, soft, and granulated, both on the surface, and internally, where the morbid process had extended over nearly the whole of the pyramids, destroying their normal appearance.

Fluids:—1st. Ascitic, specific gravity .. 10.20
2nd. Cystic ditto .. 10.10

The first had an oily or glairy appearance, owing to the presence of myriads of the tubular crystals of cholesterine, as verified under the microscope. This fluid also deposited a much larger amount of albumen by nitric acid.

SHEFFIELD MEDICAL SOCIETY.

Fourth Meeting.—Nov. 16, 1848.

The President, Dr. BARTOLOME, in the Chair.

CHOREA.

Dr. Elam read a paper on chorea. The disease now known by the name of chorea seems to be perfectly distinct in its nature from that to which the name chorea or chorea Sancti Viti was originally applied; very little is known of the latter by practical experience in the present day. It was a much more formidable disease, and frequently fatal, but we have no records by which to ascertain its pathology. The cases to be related are all of the modern chorea. Cullen's account also differs from the present type of the disease in several particulars; with regard to the voluntary nature of the actions, which should rather be described as automatic, the too prominent limitation of the convulsions to one side, and the comparison of them to the gestures of actors. Sydenham's description approaches more nearly to the present type.

Dr. Elam related a case bearing upon the question as to how far these motions may be considered voluntary, and regarded the case as pointing to the probability that they are rather of an automatic character, similar in nature to the action of the respiratory muscles.

E. D., 9 years of age, had been suffering from chorea for three weeks. When sitting up in bed, taking her breakfast, the peculiar distinction between the voluntary and automatic motions was remarked, for whilst eating, the right arm acted regularly in carrying the spoon to the mouth, whilst the left arm and both legs were violently convulsed, yet not a drop of the food was spilled; but when the girl, instead of eating instinctively, as it may be called, was told to do anything with the right hand, or asked to give her hand, she did it in the jerking irregular manner so characteristic of this affection.

The effect of music upon the ancient form of St. Vitus's dance seems to indicate that whilst volition has but little influence in itself in controlling the irregular actions of the muscles, yet by external agencies acting through the senses, an instinctive modification of these actions may take place, and if persevered in, the habit may be broken altogether. Another peculiarity in these motions is that in defiance of their apparent irregularity, there is a sort of rhythm or order,—a series of actions recurring with greater or less constancy. This is most manifest in the milder forms. In some cases it is confined to a periodical

twitching of some one or more muscles of the face or eye-balls. In one case both eye-balls were turned so far upwards and laterally, as almost to hide the iris. This, and a corresponding twitch of the orbicularis, were the constant and only symptoms, and recurred with tolerable regularity every forty seconds. As the cases become more violent, the regularity of the motions becomes less evident, one class of spasms interfering with and modifying the others; in one very violent and fatal case, however, the recurring character of the convulsions was evident almost to the last.

For the production of these motions, if they are acknowledged to be of this character, there must be a stimulus acting upon the extremities of an excito-motor nerve, and the impulse reflected from the motor centres upon the muscular system. In health, stimuli of a certain character are constantly applied to the extremities of these nerves. To produce disease, either the stimulus must be increased in intensity, or the extremities of the nerves must be in a more irritable condition, and to the latter cause must the production of chorea be almost invariably attributed. In almost every case the cause must be looked for in some local or general excitability (perhaps from irregular distribution of blood,) in the extremities of the excito-motor nerves, compelling them to respond in a more vigorous, and consequently, irregular manner, to the ordinary physical agents. It seems probable, too, that this excitability is almost exclusively manifested in the alimentary canal, the uterus, or the skin.

Dr. Elam then related several cases in which the alimentary canal was almost exclusively involved, and stated, as a general rule, that when the stimulus is in excess the spasms are tonic, giving rise to *cramp*, but when the excitability of the nervous extremities is increased, they are clonic. The next case was one of a more complicated character dependent on irritability of the peripheral nerves of the intestines.

E. S., aged 8, suffered from the usual symptoms of chorea. Purgatives and carbonate of iron were prescribed, and though the tumid bowels were relieved, the jactitations were only rendered more violent. Every variety of tonic was tried, and each successive change in the medicine seemed but to aggravate the characteristic symptoms. The pupils having become more dilated, and more insensible to light, with pain in the head, a blister was applied to the neck, and the result was a great aggravation of the symptoms. At last mercurial liniment, with opium, was rubbed over the abdomen, and the improvement was immediate. Tonics were now given with good effect, and the recovery was complete.

Dr. Elam next detailed several cases connected with affections of the uterus. These cases generally occur when the function of menstruation is instituted. There are, however, many striking exceptions to this rule. The following is an instance:—

A little girl, 8 years of age, was attacked with symptoms of inflammation of the uterus. There was pain in the hypogastric region, and a purulent discharge from the vagina, though no mischief could be detected in the vagina itself. A rather firm tumour could be felt just above the pubes, which seemed to be the uterus enlarged;

treatment directed to this part removed the tumour, the discharge, the pain, and the chorea.

Two fatal cases were mentioned, they were of the uterine nature, about the same age, and with very similar symptoms.

J. C., aged 15, ill two weeks. When first seen the convulsions were very violent. She could give no account of herself, and her friends could give little more. It was impossible to ascertain whether any local affection existed. The agitation was so extreme, the distress of the countenance so terrible, that an experienced surgeon said, "If I must die of a convulsive disease, let it be tetanus rather than this." This continued quite unchecked by treatment for ten days, when she died.

The *post-mortem* appearances were peculiar, but confined to the brain, spinal cord, and uterus. All the vessels on the surface of the brain and spinal cord were extremely gorged with blood, but this seemed to be rather an effect than a cause of the violent and long-continued agitation. The apparent origin of all the mischief was found in the lining of the uterus, which was extremely congested, and in one or two places a minute drop of blood had oozed out, indicating that the function of menstruation was just on the point of being set up, and if the patient could, as Dr. Watson suggests in fever, have been kept alive a little longer, she would ultimately have recovered. The system was on the point of relieving itself, but nature gave way in the effort.

The second fatal case was very similar to the one just detailed, both in the symptoms and *post-mortem* appearances.

In conclusion, Dr. Elam noticed the great similarity between chorea and tic, both as to their causes and the plan of treatment most successful in both. One attacks the motor and the other the sentient nerves; both are chiefly dependent on derangement of the intestinal or uterine functions,—both are generally diseases of debility,—both relieved by tonics,—and both are almost incapable of relief by narcotics.

NOTES ON AMERICA: ITS MEDICAL SCHOOLS AND ESTABLISHMENTS.

By EDWARD HUMPAGE, Esq., M.R.C.S., Bristol.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

Having, during the last autumn, spent some time in the United States, I thought a short account of what I saw there, in the professional world, would not be disagreeable to your readers. My notes are desultory, but they have the merit of being made on the spot.

In my professional intercourse with our transatlantic brethren, I can bear abundant testimony to the truth of Dr. Wood's sentiments, as recorded in the Journal of September 6th, at the Bath Association dinner, where he says,—“I may venture to say that in our land (the United States,) there prevails, almost universally, among the well informed, a kindly disposition towards the mother country.” This feeling exists

most remarkably among the members of the medical profession, among whom I was received with the greatest cordiality and brotherly kindness. Professor Valentine Mott, of New York, and Dr. Channing, Professor of Midwifery, at Boston, were foremost in their attentions, and I shall ever feel towards them lively impressions of regard and esteem.

I propose giving you a short account of the medical schools, and the profession generally in New York, and afterwards some account of the great quarantine establishment at Staten Island, and conclude with my visit to Albany and Boston, in both of which cities are thriving medical schools.

I am, Sir, yours faithfully,

EDWARD HUMPAGE.

NEW YORK.

In this splendid city there are two medical schools. The larger one called the University Medical School, is a noble edifice, with a front of hewn granite, 75 feet long. Its portico is supported by four splendid granite columns. The buildings contain three spacious lecture-rooms, with a reading-room, library, and museum, the latter not as yet very rich in specimens. The number of pupils is about 400. The winter session begins in October, and ends in February. Valentine Mott, and Granville Sharpe Pattison, are the stars of this school, and their pupils come from all parts of the Union, and also from South America. The remarkable mixture of Anglo-Saxon, genuine Yankee, and pure American expression of countenance, gave me at once the feeling that I was not in Old England; and this was increased by the singular number of men in middle life which were to be seen among the pupils,* diligently noting down the practical sayings and simple prescriptions of Professor Mott.

I had the pleasure of hearing several of the introductory lectures, which are delivered before an audience of six or seven hundred persons, including many of the higher class of citizens.

The arrangements for lectures and dissections are pretty much the same as our own, but the fees very much lower. I had the satisfaction of being present at Professor Mott's weekly public clinique, which is conducted by him in the anatomical theatre of the school, and to which all the pupils are admitted.

This worthy professor gives his advice to all who come, commenting on the patient just as the case presents itself. We had on one occasion, a young Irishwoman: her case was hare-lip, and a very favourable one for operation. “Ah!” said he “why didn't you get your beauty improved in old Ireland?” “An' faith,” said she, “they did not laugh at me there, but here they do. Please, your honour, to cure me.” In a very short space of time the scissors and ligatures were prepared by Dr. Mott's son-in-law, Dr. Van Buren, and

* This is explained by the fact, that many men in the States having made some money by farming, or in trade, resolve to become *doctors*, and forthwith enter the ranks of pupils, hear lectures, perhaps, for two sessions, and then go into the “Far West” and practice physic.

the patient being seated, the operation was commenced by separating a portion of the lip from the malar bone; then the edges were cut with the scissors, the edges brought together, and two sutures (he much prefers them to pins,) applied, over which was placed a *single piece* of adhesive plaster, shaped to the part, the ends reaching to the anterior edge of the lobes of the ears, thus making a most secure support.

The operation was very neatly performed, the labial arteries being compressed by the assistant; not a tablespoonful of blood was lost. The various steps of the operation were commented on to the class, the professor remarking that great care must be taken at the time of the removal of the stitches, (on the sixth or seventh day,) to support the part well with the finger and thumb, until another piece of adhesive plaster could be applied. This, he remarked, in children, was most essential, and if neglected would lead to a complete failure.

After this operation Dr. Mott exhibited the amputated leg of "a brother chip" as he facetiously styled him, who unfortunately fell from a height the day before, and to whom the Doctor was summoned. He found a compound dislocation of the right ankle, *without much contusion*. Amputation was considered necessary. I had an opportunity of telling Dr. Mott afterwards, that we in England should have attempted the preservation of the limb, and that it was generally successful. His reply was, "I know it; but here we get tetanus almost invariably, and then death is inevitable." Of course I could make no reply to that. The case went on very well, as I found by subsequent enquiries.

I saw several cases of spinal disease in children, from two to six or eight years old; they are by no means uncommon, and are regarded as depending on sub-acute meningitis of the arachnoid envelope, producing paraplegia. The treatment consists in the occasional application of three or four leeches, followed by small blisters and strychnine. In other cases they find tonics, as iron, quinine, or iodine, useful, with the local application of nitric acid, just to raise the epidermis, but these cases are very intractable, and their treatment unsatisfactory.

Professor Mott concluded the morning's clinique by some excellent observations on the conduct of pupils at the commencement of their career, urged the necessity of uprightness of conduct, and kindness to the poor. "I, (said he,) was content to go for a long time, into the cellars of the poor, before I ascended the marble steps and stood under the porticos of the wealthy, and you must do the same; there is no royal road to the high places of our profession, begin humbly and rise gradually."

(To be continued.)

General Retrospect.

ANATOMY AND PHYSIOLOGY.

BLOOD CORPUSCLES OF THE HUMAN EMBRYO.

Mr. Paget has examined the blood of a fœtus of four weeks old, which is the earliest period at which it has been submitted to microscopic enquiry. The great majority of the red corpuscles presented a circular outline, and as they rolled over appeared spheroidal and vesicular. Their surfaces were smooth, and as they dried, portions of their edges were incurved and folded towards their centres. They were apparently more deep-coloured than in adult blood. The nuclei were circular, with well-defined dark outlines, and darkly nebulous, as if granulated. All the corpuscles were nucleated; some contained two nuclei, and were ovoidal, and larger than the rest.

The measurements of the spheroidal corpuscles were from 1-2100 to 1-2800th of an inch in diameter; that of the nuclei from 1 3700 to 1-4500th. Of the bi-nucleated cells the measurements were 1-1500 by 1-2300th of an inch.—*Medical Gazette*, February 2nd.

PATHOLOGY AND PRACTICAL MEDICINE.

ABSCESS OF THE PITUITARY BODY.

The following uncommon case is reported by Dr. Heslop:—

J. H., an engineer, of active habits, was attacked with acute headache after dancing all night on February 10th, 1848. Previously to this he had exhibited a remarkable tendency to sleep; if he sat down he would immediately fall into a heavy slumber, but the sudden acute pain was the first symptom which attracted attention. After using some domestic remedies the pain was much relieved, but it returned in consequence of error in diet. He became wild and restless, or at other times would lie in a state of semi-stupor, silent, and indifferent to everything. He on one occasion stripped himself and evacuated the bowels in the centre of his room. Mercury was now given, and leeches and blisters applied, but in spite of this he fell into profound coma, and the pulse became intermittent and fell to 40 in the minute. Wine was now given freely, and he rallied so much that recovery was confidently expected. Two symptoms remained, of bad import: one of them was an almost total loss of memory, the other loss of power over the sphincters. He was, however, well enough to go to Dublin, where he was placed under the care of Dr. Stokes. The progress of the disease was marked by emaciation, and further declension of the memory; the orbicularis of the right eye also became paralysed, the acute pains in the head continued to the last. The immediate cause of death was an obscure attack of pleurisy in September.

Post-mortem examination. Body emaciated; membranes of the brain healthy; at the second pair of nerves was found a soft dark grey tumour, the size of a walnut, occupy the site of the pituitary body, and extending posteriorly and laterally; it contained a dark red purulent fluid. It filled up the entire outer peduncular space, extending backwards to the pons Varolii, and

protruding forward to the fissure of Sylvius. The crura cerebri were pressed outwards. Underneath the tumour a quantity of thin reddish fluid was noticed. The bones which formed the middle cerebral fossæ were covered with small sharp osseous processes.—*Dublin Quarterly Journal*, Nov. 1848.

ATALECTASIS PULMONUM

The author of this communication, Dr. Friedleben, attempts to shew that atelectasis (the fetal state of the lungs,) is always produced by some obstacle to the complete establishment of respiration. He maintains that this pathological condition is not confined to new born children, but is also met with in infancy.

The anatomical characters of the lesion consist of a brownish colour of a portion of lung which has not respired, and is distinctly separated from those which have admitted air. The brown portions are hard, and do not crepitate, and sink in water. They can be artificially inflated, and in that case closely resemble healthy lung. Amongst other alterations are observed an abnormal quantity of mucus in the bronchial tubes, the foramen ovale open, the presence of coagula in the cavities of the heart, friability of the liver and spleen, injection of the cerebral vessels, and in some instances true apoplectic effusions.

The diagnosis of atelectasis pulmonum is easy, if we compare the physical with the rational signs. When the disease has lasted a few days, cyanosis always declares itself, less in consequence of the patency of the foramen ovale, than as a result of deficient hæmatisation. The author notices all the circumstances which modify the progress and termination of the malady. The latter is not always immediately fatal, but in some cases persists to infancy. It is to an attack of bronchitis in the fetal state, that this persistence is, in the author's opinion, to be attributed, by which the bronchial ramifications are impeded, and the entrance of air prevented.

The anatomical differences in this case between the sound and diseased lung become very marked, the latter appearing of a dirty violet colour, like that of the cortical portion of the kidney; the pleura covering it is also thicker, and insufflation is difficult or impossible. The consecutive lesions most frequently observed are dilatations of the right ventricle, amplification of the foramen ovale, effusion into the pericardium, œdema of the lungs and cellular tissue.

The lengthened details into which the author enters respecting the anatomical appearances in atelectasis have chiefly reference to the diagnosis from fetal pneumonia, and are intended to prove that it is essentially the same lesion which French writers have described as *carnification* of the lung.

The author thinks that he has been able to distinguish three forms of the malady. In the first, the infant has mucous rales and cough immediately after birth, but it sucks well; later, paroxysms of coughing come on, with threatened asphyxia, and a livid colour of the face. These attacks end in abundant vomiting, and the child then resumes its wonted appearance. There is a dull sound on percussion, over several points of the chest, with a bronchial souffle; in the other

portions of the lungs, mucous rales and puerile respiration are heard. After a short time the heart begins to beat irregularly, then the impulse becomes more feeble. At the same time, the lips and extremities become hard, the features swollen, and the respiration embarrassed. The fits of coughing also become more frequent and prolonged, œdema of the lungs follows and death ensues, with symptoms of cerebral effusion.

The second form is characterized by less violence at first, but is speedily complicated with symptoms of pneumonia, and death ensues even more rapidly than in the preceding.

The third form is the most rapidly fatal. The infants at birth have a slight cough; but fever is suddenly lighted up and is accompanied with symptoms of follicular enteritis. In this form the infant appears to die of exhaustion.—*Archiv für Physiologische Heilkunde*

CONCLUSIONS RESPECTING THE MODE OF PROPAGATION OF CHOLERA IN RUSSIA, 1847-48.

Dr. Frettenbacher, of Moscow, in an elaborate statistical report of the progress and ravages of cholera throughout the Russian Empire, during the last two years, gives the following general conclusions as the result of his observations on the subject of its propagation:—

1. Intermittent fevers had prevailed throughout the whole extent of the Empire, previously to the appearance of the cholera. In 1846 they had assumed in many places an epidemic character. In 1847, when the cholera appeared these fevers ceased, and they reappeared as the cholera declined.

2. The cholera was preceded, almost invariably, by disorders of the digestive organs and intestinal canal. These derangements increased with the appearance of cholera, and decreased in severity as it disappeared. They prevailed throughout the whole extent of Russia in Europe, even where cholera was not present.

3. The cholera followed the course of large rivers and the chief lines of human intercourse. Prevailing winds had no influence on its progress.

4. When the cholera appeared in places out of its principal route, it was generally found to have manifested itself shortly after the arrival of persons from districts where the disease was prevailing.

5. In localities where the cholera was thus conveyed by individuals, it did not always spread as an epidemic, but those only who came in contact with the affected had the disease, and if it did spread epidemically under these circumstances, its progress was very slow.

6. In many places the cholera appeared in an epidemic form, without any communication with infected districts, under the influence of general causes, of which we have as yet no satisfactory explanation.

7. The cholera propagated itself especially in low situations, in unhealthy and confined dwellings, where the inhabitants were previously debilitated by disease, intemperance, and other depressing causes.

8. Some localities which, from accidental circumstances, were carefully isolated, such as large establishments, and even entire villages, completely escaped the visitation.

The preceding facts prove that this disease, originally epidemic, may become energetically contagious, or, in other words, communicable from man to man.—*Gazette Médicale*, Jan. 13, 1849, and *Medical Gazette*, February 2nd.

TREATMENT OF MALIGNANT CHOLERA.

The following comparison of various modes of treating malignant cholera, is taken from a review of several recent writings on this disease in the *Monthly Journal*, 1849:—

Bloodletting. In reference to this the evidence is conflicting. It has been employed with alleged benefit in all stages of the disease in this country and in India. In the early stage it has been effectual in relieving the feeling of oppression on the chest. Its effect on the mortality is not evident. Dr. Robertson, in his statistical account of the cholera in Edinburgh, during the present epidemic, states that he has in many instances prevented collapse by this measure.

Stimulants. According to Mr. Ross's tables, stimulants given to any extent appear to have been injurious.

Opium. There seems no reason to doubt its efficacy in the early stage, but according to the tables above mentioned it does not diminish the mortality.

Mercury has not been followed by remarkable success, in this country, excepting in the hands of Drs. Ayres and Peacock, both of whom use it without stimulants. In their experience the mortality was reduced to thirty-one per cent. Dr. Fleming advises the use of a solution of the bichloride, as more readily absorbed.

Tartar Emetic in small doses, with cold water *ad libitum*, has, in the Droitwich Asylum, afforded the largest per centage of cures, the deaths being only four in twenty-four cases.

Injection into the Veins has afforded no satisfactory results.

Chloroform has been used by inhalation in thirty-seven cases. The results are inferior to those witnessed in the Droitwich Asylum, but superior to the general results exhibited in Ross's tables.

NUX-VOMICA IN THE DIARRHŒA OF EXHAUSTION.

Dr. Nevins has alluded to the benefit derived from the exhibitions of nux-vomica in pauper patients labouring under exhausting diarrhœa. His formula is:—Alcoholic Extract of Nux-vomica, gr. ss.; Rhubarb, gr. ss.; Saccharine Carbonate of Iron, gr. j.; Blue Pill, gr. ss.; Opium, gr. $\frac{1}{8}$; in a pill three times a day. He attributes the benefit derived to the action of the nux-vomica in stimulating the nervous power of the intestines, and thus enabling their lacteals to absorb the nutriment from the food. At the same time the small doses of blue pill and rhubarb improved the secretions, and the iron acted as a tonic.—*Med. Gazette*, Dec. 15, 1848.

LEMON JUICE IN RHEUMATIC GOUT.

Dr. Owen Rees narrates the case of a girl, aged 18, suffering from rheumatic gout in all her joints, who was treated successfully by lemon juice, in the dose of half an ounce three times a day. In his remarks on the case, he states that he has in many other cases seen

marked and rapid relief from the same plan. He first had recourse to lemon juice from a belief that vegetable acids, from the large quantity of oxygen they contain, contribute to effect the transformation of the tissues generally, and moreover, from the idea that the super-citrate contained in the juice, by its transformation contributed to the alkalinity of the blood.—*Medical Gazette*, Jan. 26th.

SURGERY.

CASE OF CONGENITAL GLOSSOCELE OR HYPERTROPHIED TONGUE.

Mr. Delaney, of the United States navy, relates a case, of which the following is a condensed account:—

Miss F., aged 20, was born with the tongue protruding from the mouth. It had subsequently grown, and at the present date was a disgusting nuisance. She is in health, and has no engorgement of the sub-maxillary glands. The protrusion is upwards of four inches, circumference seven inches, and thickness in the middle two inches; a deep linear fissure occupied the whole length of the dorsum. The protruded portion was quite dark, owing to a number of vesicles filled with blood. The substance of the tongue was extremely hard, and very insensible; it constantly poured out a viscid offensive secretion. The inferior maxilla was natural in form, excepting at the symphysis, where the incisors and canine teeth were separated half an inch, and inclined outwards by the pressure of the tongue. The lower lip was also everted.

After due consideration, amputation was decided upon, and performed in the following manner:—The patient being seated in a chair, and her head supported by an assistant, and her hands secured, the tongue was forcibly drawn forward, and a ∇ incision commenced on the left side, and carried to the median line, and then cut out on the opposite side, thus, with two strokes, excising the part. A formidable jet of blood immediately followed from the dorsal and canine arteries, which required a ligature.

The patient suffered so little pain, that immediately the ligatures were fixed, she ran to a looking-glass to see the effect of the operation. The flaps were brought together and secured by four interrupted sutures. When this was done the tongue was of good shape; the length removed was two inches and three quarters. For nine hours after the operation the tongue remained within the mouth; inflammation and swelling then set in, and caused it to protrude. The only dressing was lint wet with iced water. On the sixth day three of the sutures were removed, and on the twentieth complete union had taken place.

Miss F. soon after chewed her food for the first time with the tongue in the mouth, and it now keeps within the teeth like a normal tongue. The patient is now a comely girl, the teeth having been removed and replaced by artificial ones.—*American Journal of Medical Sciences*, October, 1848.

NEW OPERATION FOR VARICOCELE.

The author, Dr. Gross, has performed this operation eight times; the patients were all young men and recovered without a bad symptom.

The scrotum, previously divested of hair, is rendered tense by grasping it behind with the left hand. A vertical incision, an inch in length, is made over the anterior part of the tumour, down to the enlarged veins, which are then carefully isolated from the duct, artery and nerves. This is the first part of the operation. The second consists in passing a short thick needle underneath two or three of the larger trunks, and winding around it a stout thread, either elliptically or in the form of the figure 8. The ligature is drawn tight, and the operation is concluded by closing the wound with sutures or plaster; the patient is now put to bed, and light diet enjoined. At the end of twenty-four hours the blood is sufficiently coagulated in the obstructed veins to justify their division, which is then done with a bistoury, and the needles are removed. The patient may usually be permitted to sit up in four or five days.

The advantages of this operation are its simplicity and facility of execution, its freedom from pain and hæmorrhage, the certainty of avoiding the artery, nerves and duct, and the rapidity of cure.—*American Journal of Medical Sciences*, October, 1848.

PHARMACY.

SOLUTION OF CAMPHOR IN CHLOROFORM.

Messrs. Smith, chemists, of Edinburgh, have made known that camphor will dissolve in chloroform in almost any proportions. [We have verified this, and now frequently prescribe a solution, ten drops of which contain three grains of camphor. The discovery enables us to give larger doses of camphor in solution than was previously possible.—Ed.]

TOXICOLOGY.

POISONING BY CHLORIDE OF ZINC.

Dr. Stratton narrates two cases of poisoning by a solution of chloride of zinc, taken under mistake for whisky. The symptoms were those of irritative poisoning. The first case recovered spontaneously; in the second he administered soap-suds as an antidote, with effect. He suggests this, or a solution of carbonate of soda or potash, as the proper antidote in such cases.—*Edinburgh Medical and Surgical Journal*, Oct., 1848.

THE LATE ACTIONS AGAINST THE MIDLAND RAILWAY COMPANY.

COX v. MIDLAND RAILWAY COMPANY.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

I beg to offer you my best thanks for the interest you have taken in this case. The enclosed correspondence will be an answer to your question (page 76, line 26)—“Now, we beg to ask, first, whether the innkeeper, &c.”

The innkeeper has not been paid; the Surgeons have not been paid; and, in defiance of public opinion, the

Company have applied to me for *their costs* in the action, although a verdict was given in my favour by Mr. Justice Maule, at Warwick.

Yours, obliged,

WILLIAM SANDS COX.

To the Editor of *Aris's Gazette*.

SIR,—Having observed in the *Times* of Tuesday last, and in the *Birmingham Journal* of to-day, a letter from Mr. Bell, Secretary of the Midland Railway Company, which contains matter directly opposed to facts; and as I happen to be in possession of letters from my Counsel (Mr. Hayes,) which support my previous and present statements, I beg to send copies to you, trusting you will be good enough to give them publicity.

At the late trials the Company did not attempt to deny negligence. They did not, either at Warwick or in the Court of Exchequer, pretend that they had paid the Doctors or Innkeeper, but they set out with saying that the charges were unreasonable, and finding that that ground would be cut from under them, they, to the surprise of every one, resorted to the desperate defence that the calling-in of the Doctors and employment of the Innkeeper were contracts, which required the seal of the Company to be binding.

Mr. Bell has thought proper to advert, with no little censure, upon my conduct in this matter; but after the letters from my Counsel are laid before the public, I shall with confidence leave the matter with them to judge if my conduct has been such as Mr. Bell states, or “calculated to carry anything but a correct notion either of the facts of the case or of the conduct and motives of the Directors and Officers of the Company.”

I am Sir,

Your obedient servant,

GEORGE CHILWELL.

Old Square, Birmingham, Feb. 3, 1849.

Temple, September 29, 1847.

DEAR SIR,—I shall not have an opportunity of seeing Mr. Macaulay for some time to come, but will mention the subject of your note on the earliest occasion.

I don't think Mr. Davies will be affected by Higgins's verdict, as it was clear he never gave credit to Higgins, but attended in consequence of being sent for by the servants of the Company. It was understood between Mr. Macaulay and myself that the Company would settle for medical attendance, provided such charges were reasonable, with regard to the situation in life of the patient.

I remain, dear Sir, yours truly,

G. HAYES.

G. Chilwell, Esq., Solicitor,
Old Square, Birmingham.

Temple, November 13, 1847.

Higgins and the M. R. Company.

DEAR SIR,—At the trial it was understood between Mr. Macaulay and myself that the amount agreed to be paid to Higgins was *exclusive of Medical and Surgical charges*. Mr. Macaulay stated that all reasonable charges of this nature would be paid by the Company; but he did not say they would pay the particular bills referred to by you, but on the contrary stated that the Company had complained of the amount of some of the bills sent in as excessive, considering Higgins's situation

in life. The question of medical charges was one with which Mr. Whitehurst and I considered we had nothing to do as the counsel for Higgins, for it appeared that the medical men had been sent for by the agent of the Company, and that they had given credit to the Company, and not to Higgins.

I should conceive the best way would be for the medical men to refer the Company to the arrangement and admission made by Mr. Macaulay at the trial, that the Company would pay the medical charges. The Company, or their solicitor, will then refer to Mr. Macaulay for information, and his answer will come in a regular way before the directors. The directors, on receiving this answer, will no doubt admit their liability to pay medical charges, but the question of *amount* is a matter entirely to be settled between the medical men and the Company. I have not yet had an opportunity of seeing him with respect to Higgins, but will do so in a day or two.

Yours truly,

G. Chilwell, Esq., Solicitor, G. HAYES.
Old Square, Birmingham.

Temple, January 10, 1848.

DEAR SIR,—The medical men's charges is a matter between *themselves* and the Company, and to whom I have always *understood they gave credit*. This was the reason why I considered that it was proper to omit the mention of it in the memorandum of settlement, which was entirely a matter between *Higgins* and the Company, and the medical men not having given credit to Higgins he had nothing to do with their claim. You are not acting prudently, or indeed correctly, in corresponding with the Company as if it were an affair belonging to the action of *Higgins and the Midland Railway Company*, as their letters, and I presume your's, are entitled.

If the medical men have a good case by way of evidence to fix the Company, (as I was informed,) they may sue the Company as their employers, but I have no means of knowing whether this is the case, and cannot advise on such a point by letter, having neither time to write nor any facts to enable me to judge.

I remain, dear Sir, yours truly,

G. Chilwell, Esq., Solicitor, G. HAYES.
Old Square, Birmingham.

Extract from a Letter of John Suckling, Esq., Solicitor to the Plaintiff, addressed to Aris's Gazette.

"In the first place, the accident happened through gross negligence on the part of the Company; this has not been denied either at Warwick or at Westminster. It has been proved over and over again, that the Company's servants sent for Dr. Davies, from Coleshill. The first question Dr. Davies asked the messenger was, 'who sent for him; and the answer was, 'the Station-master.' On this Dr. Davies went to Whitacre. Four medical men attended the man; and, after a consultation, the Station-master at Whitacre attempted to telegraph the Superintendent at Birmingham to send Mr. Sands Cox to join in the consultation. The intense cold and snow having rendered the telegraph useless, Mr. Davies, the surgeon, went to Birmingham for Mr. Cox, and consulted Mr. Needham, one of the Company's chief clerk's there, who fully approved of what had been done, and put on a special carriage for Mr. Cox's accommodation, which, I believe, was taken off at Whitacre, and kept there until Mr. Cox returned. And on two subsequent occasions Mr. Needham sent Mr.

Cox to Whitacre, free of fare, to see how the man was going on.

"Neither Dr. Davies nor Mr. Cox gave credit to Higgins for their services. Mr. Cox knew nothing of Higgins; he trusted the Company. The Company, through their counsel, promised that Mr. Cox's reasonable charges should be paid. His charges have been admitted to be fair, and that they ought to have been paid there cannot be two opinions.

"The defendants appear to estimate the value of a poor man's leg at £100, no matter what his occupation, or whether he has a family or not; but I can tell them that in this case, after the doctors, innkeeper, and attorney had been paid, nothing like that sum would have remained.

"JOHN SUCKLING.

"Birmingham, Feb., 3, 1849."

PRACTISING DRUGGISTS.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

I wish to make known a fact or two respecting the medical and surgical practice carried on in this city, for it has been said, and, probably, with some approach to truth, that one-fourth of the practice in Bristol is in the hands of the druggists.

A child, one year old, was brought to me on the 31st of January, with the lids of both eyes in a very swollen state. Upon opening them, I found that the cornea of each eye had sloughed completely, and the contents of the globes were escaping.

The mother stated that the eyes had been perfectly sound a fortnight before, but seeing that they were slightly weak, she took it to a druggist in this city, who, after examining the eyes and mouth, told her there was not much amiss, that it probably depended on the teeth, and finished by selling her a bottle of "lotion-water." The child is of course hopelessly blind, but the constitutional symptoms arising from the disease of the eyes have so injured its health, that it appears scarcely likely to live, a termination of the case much to be hoped for.

I have, before now, entered the shop of another druggist here, and found him examining a child's mouth, and prescribing powder; another I have seen paying his daily visits; and within the last ten days, whilst enquiring about the composition of a purgative dose for infants, I have received a lecture from a shop-boy behind the counter, upon the facility with which very young children bear doses of calomel.

It is not on account of the profession, so much as for the sake of the poorer part of the public, that I wish to draw attention to this state of things.

I remain Sir, your obedient servant,

AUGUSTIN PRICHARD.

Red Lodge, Bristol.

QUEEN'S COLLEGE, BIRMINGHAM.

Owing to unavoidable circumstances, the decision of the prizes for the last collegiate year was not given till a few days since. At a special meeting of the Council, the following gentlemen were announced as the successful candidates:—

Anatomy and Physiology:—(Medal)—Mr. Thomason, Shiffnal.

Practice of Physic:—(Medal)—Mr. Whittle, Leamington; (Hon. Certificate)—Mr. Moore, Hales Owen.

Surgery:—(Medal)—Mr. Whittle, Leamington.

Materia Medica:—(Medal)—Mr. Blake, Birmingham; (Hon. Certificate)—Mr. Low, Birmingham.

Chemistry:—(Medal)—Mr. Blake, Birmingham.

Midwifery:—(Medal)—Mr. Lane, Grosmont; (Hon. Certificate)—Mr. Stead, Congleton.

Forensic Medicine:—(Certificates)—Mr. Mills, Tipton; Mr. Partridge, Darlaston.

Demonstrator's Prize:—Mr. Moore, Hales Owen.

Warneford Essay:—"On the Articulations of the Human Skeleton." Mr. Lane, Grosmont, (1st.); Mr. Dunn, Birmingham, (2nd.).

Governors' Gold Medals:—Mr. Lane, Grosmont; Mr. Jones, Cleobury Mortimer.

ROYAL COLLEGE OF PHYSICIANS.

LECTURES.

The Gulstonian Lectures will be delivered by Dr. Gull, and commenced on the 16th inst.; the Croonian, by Dr. Conolly, on the 28th; the Lumleian, by Dr. Todd, March 9th; and the lectures on Materia Medica, by Dr. G. Bird, March 21st.

SOCIETY OF APOTHECARIES.

Gentlemen admitted Licentiates Thursday, February 1st. :—Oglethorpe Wakelin Barratt, Birmingham; Francis Turner Welby King, Melton Mowbray; Felix Weekes Richardson, Banbury; William Thomas Garrett Woodforde.

OBITUARY.

Died, January 20th, at Canterbury, aged 92, Francis Dalley, M.D., formerly of Stamford.

February 2nd, at Montrose, aged 42, David Burnes, M.D., formerly of London.

February 3rd, at Hornchurch, Essex, Robert Wm. Quennell, Esq., Surgeon.

February 4th, at Madeira, Nicholas George Hobson, Esq., Surgeon, late of London.

February 6th, at Ashburton, Devon, aged 52, John Soper, M.D.

TO CORRESPONDENTS.

Communications have been received from Dr. Copeman; Dr. Kingdon; Mr. Humphry; Mr. Humpage; Mr. Waldron; Mr. Spooner; Dr. Ballard; Professor Sands Cox; Mr. A. Prichard; Mr. T. L. Walford; Dr. Butler Lane; Mr. Nunneley; Dr. Heaton,

PROVINCIAL MEDICAL & SURGICAL JOURNAL.

A COURSE OF LECTURES ON SURGERY,

DELIVERED IN THE

MEDICAL SCHOOL OF CAMBRIDGE.

By GEORGE MURRAY HUMPHRY, Esq., Downing
College, Surgeon to Addenbrooke's Hospital.

LECTURE IV.

Antiphlogistic Treatment; Local Applications; Treatment of preliminary Depression; Stimulants in early Stage of Inflammation; Chronic Inflammation, Treatment of, by Depletion; Ill effects of too much local Depletion; Mercury: Attention to General Health; Ill Effects of long-continued Poulices; Strong Irritants; Exercise of the inflamed Part, to be enforced in Hysterical Cases, and sometimes excited by Electricity; Counter-Irritants, Mode of Action, when to be employed, and in what Form; Issues; Pressure.

The general antiphlogistic treatment comprises a variety of measures, intended as auxiliaries to bleeding, in subduing inflammatory fever, such as aperients, diuretics, sudorifics, more particularly antimony, (which, besides its lowering effect upon the system, is supposed to possess some direct anti-inflammatory property,) and saline medicines. To these are added sparing diet, rest in the recumbent position, and elevation of the inflamed member.

The local applications best adapted to the relief of acute inflammation situated below the surface, as in the knee-joint, are those which combine the soothing influences of warmth and moisture, at the same time that they promote perspiration, and prevent chafing and irritation of the tender part. The continued application of warm fomentations or poultices upon the skin over an inflamed joint, no doubt exerts considerable influence in allaying the disease; they are, on the whole, more generally beneficial than cold lotions, but the sensations of the patient will often guide us aright in our choice between these opposite measures. When the inflammation attacks the surface, as in cutaneous erysipelas and superficial burns, great relief is afforded by dredging the part all over with flour; this is often more agreeable to the patient, as well as more cleanly, than either warm fomentations, cold lotions, or carded cotton. I suppose it acts in the same manner as oil, by screening the inflamed and smarting skin from the irritating influence of the air.

I have endeavoured to point out the general principles only of the treatment of acute inflammation with inflammatory fever, and must leave you to fill up the detail, and gain a further acquaintance with this, the most important branch of your study, where alone it can be effectually done, at the bed-side of the patient. There you will see the mischief of treating diseases by name, of commencing the indiscriminate use of the lancet, and pouring in volleys of calomel and opium, of purgatives and saline medicines, because an affection is pronounced to be inflammatory. You will discover the necessity of modifying the treatment according to the symptoms of each particular case, and the powers of the patient, and the advantage of occasionally adopting the humbling and difficult resource of leaving the case entirely to nature's therapeutic skill.

Occasionally we are called to a patient during the preliminary stage of his illness, before its particular features have declared themselves. We find him feeble, chilly, and miserable; some kind of attack is evidently impending, but we cannot tell what it may prove, or where it may be displayed. Under such circumstances we can only treat the existing symptoms, and by applying warmth and stimuli of various kinds, endeavour to rouse the system, so as to break the first appreciable link in the chain of disease, and arrest it at its very commencement. A good dinner will sometimes check a rising fever, a day's hunting will prevent an attack of rheumatism, and wine whey, with a warm bed, may stop a coming cold; agreeable remedies, but unfortunately not altogether unattended with danger, and more likely to be successful when prescribed by the patient than by the medical man, who is seldom called in till the time for such proceedings is gone by, and who cannot so easily judge of the capabilities of the patient to rouse himself to exertion. We are, therefore, generally obliged to content ourselves with less decided measures and, there is no doubt, that by endeavouring to mitigate the preliminary depression, we are taking the best preventive measures with reference to the severity of the succeeding illness.

The application of stimulus to a part in which inflammation is impending, may, in like manner, occasionally succeed in arresting the incubating process, of whatever kind it be, and so prevent the subsequent stages of the disease. But we have rarely an opportunity of employing any such treatment, because the stage of depression in a part preliminary to the reaction, as I mentioned in the last lecture, is seldom to be

recognized; and the first notice of the local disease is not generally observed till the inflammation has fairly commenced.

When inflammation results from the application of a poison, as in gonorrhœa, the regular march of the disease may be sometimes broken, and the poison hurried, as it were, through its stages, or ejected from the system by a strong stimulating application, such as a solution of nitrate of silver, which is quickly followed by acute inflammation; the inflammation so excited, being freed from the peculiar influence of the poison, subsides in the same manner as it does when occasioned by any other accidental cause. To be successful this treatment must be adopted at an early period, before the inflammation caused by the poison has fairly set in, otherwise the original disease is aggravated rather than superseded by the additional inflammation; secondly, the stimulus must be strong enough to impress a new character upon the inflammation; the superadded disease must take the place of the primary inflammation, which cannot be ensured without risk to the structure of the part, if the latter have attained to any great degree of severity.

Very frequently after the acute symptoms have subsided, the inflammation lingers in a languid, sluggish, chronic condition, or it may have presented these characters from the beginning. Chronic inflammation, in its chief features, corresponds with acute inflammation; it is attended by the same disposition to effusion of serum and lymph, interstitial absorption, ulceration, and mortification, but the difference consists in the greater languor and inactivity of the process, the greater relaxation of vessels, and the more tardy current of blood through them, and the heart's action is not increased, either in force or rapidity. General bleeding is, therefore, very rarely required in the treatment of chronic inflammation; it may be rendered necessary, by other co-existing circumstances, such as a plethoric condition of the individual, but independently of these, it is scarcely ever required for the cure of the local disease itself. Abstraction of blood from the part is very often beneficial, more particularly in those numerous cases which occupy the wide intermediate space between acute and chronic disease, to which the term subacute has been applied. You will not forget that the object in these cases is rather to produce a continuous or repeated effect, than to cause a sudden impression, more relief being generally derived from the repeated application of a few leeches than from a larger number at one time, and, with a few exceptions, such as the os uteri and eyelids, they should be placed as near the inflamed part as can conveniently be done.

You must beware of continuing this treatment too long, that is to say, beyond the time during which its good effect is evident, because there can be no doubt that the repeated application of leeches tends to weaken an organ, and render it more liable to further attacks of inflammation. I am quite disposed to credit the experience of the patient at the hospital, who frequently suffers from inflammation of the eye, and who told us the other day that leeches once or twice applied afford her relief, but that a more frequent repetition of them

makes the eye weak, and protracts the period of its recovery. The injurious effects of repeated local depletion are particularly observed in the cases in which inflammation does not exceed its congestive stage, such as the determinations of blood to the head, so common about and soon after the period of puberty, attended with the sensation of fulness, as though the head would burst, which makes the patient most anxious to lose blood, and the temporary relief afforded by leeches or cupping is so great, that he is no less impatient to repeat the treatment, when the symptoms return with unabated force, and he is less able to bear them. The commencement of these symptoms may be often traced to free and repeated local depletions, instituted for the purpose of arresting some inflammatory affection of the eye or other part of the head, and they are observed most frequently in persons of languid circulation, with feeble pulse, and blue cold extremities.

Mercury is also a very valuable remedy in chronic inflammation, attended with effusion of lymph, as in chronic iritis. Its effect will, probably, require to be maintained for some time, and it should, therefore, be introduced into the system gradually, by small and repeated doses, so as to avoid the disorders caused by its more free administration. By caution in its use, the patient being under surveillance during its influence, allowed his usual exercise, if possible, and that simple diet which suits him best, mercury may be given so as to produce sufficient effect upon the system, and continued for a considerable time, without injury to the health; indeed, the patient very often improves greatly in appearance and vigour during its administration. The slightest effect upon the gums, so slight that the patient is scarcely aware of any soreness, or even of an unpleasant taste in the mouth, is sufficient, in most cases of chronic inflammation. A more powerful impression is attended with certain injury to the constitution, without corresponding alleviation of the disease.

In treating chronic inflammation more than any other form of local disease, it is essential to pay much attention to the state of the constitution, for the continuance of the malady is often dependent on some disorder of the general system, particularly of the digestive organs, which impedes our remedies, and is likely to be felt more severely, or to show itself in some other form, if the local disease be cured. It is the more important to be on the watch for constitutional ailments, because during the existence of the local disease, they are often in abeyance for the time. A patient is admitted into the hospital with a sore leg, and we should not discover that he labours under any constitutional defect, did we not learn that previous to the appearance of the ulcer, he was for some months out of health, suffering under indigestion, headache, languor, or some other symptoms, which have ceased since the existence of the local disease; perhaps we may further learn that the ulcer had appeared on several former occasions, each time being productive of relief to the general indisposition which again returned when the ulcer was healed.

Chronic inflammation is very often connected with a debilitated state of constitution, associated, it may

be, with disorder of the digestive organs, and requiring tonic treatment by medicine, or more nutritious diet, exercise in the open air, cold ablutions, &c. Exercise in the open air is so essential to the maintenance of the general health, especially of persons whose occupation is chiefly out of doors, that we are unwilling to confine them to bed unless such complete rest be essential to the cure of the local disease. I have frequently seen affections of the joints progress more rapidly to suppuration, destruction of the synovial membrane, and ulceration of the cartilages, in consequence of the routine treatment, by rest and confinement to bed, being pertinaciously adhered to, in spite of the intimations given by the pallid countenance, the failing appetite, and the increasing perspirations. It is often advisable, more particularly in mild weather, to allow the patient to move about and go out of doors, even at the apparent risk of injury to the local disease. When general exercise can be combined with rest of the affected limb by means of splints and crutches, it should almost invariably be permitted.

We employ besides, three chief local remedies in the treatment of chronic inflammation,—namely, stimulants, counter-irritants, and pressure.

Our usual intention in the employment of stimulants is to brace the weakened organ, to astringe its relaxed and dilated vessels, and to give an impulse to its nutritive energies. To effect the first of these purposes, we apply cold, either exposing the part to the air, or using cold water or lotions. Of course such treatment is incompatible with the continuance of poultices and warm fomentations, and I may take this opportunity of warning you against regarding such applications as mere negative agents, and prescribing them in a routine indifferent manner, or continuing their employment too long in cases of chronic inflammation of the skin, or in erysipelas when the acute symptoms have passed away, for the chronic stage of inflammation is very often prolonged by perseverance in these applications, which have the effect of weakening and relaxing the part upon which they are placed. Unless there be some additional cause, rendering poultices desirable, they should rarely be employed in superficial inflammations after the acute stage has passed away, and the part has acquired a blue languid appearance. I have seen several cases of chronic inflammation of the eye, with swollen conjunctiva, marked with blue dilated tortuous vessels, where the disease was evidently kept up by poultices and fomentations applied in a thoughtless manner, and which were cured merely by the discontinuance of the local treatment, and the exposure of the part to the air. The profuse discharge, and the slow healing of wounds after phlegmonous erysipelas, are not unfrequently owing in part to the same cause. It is, I suppose, from the observation of the injurious effects of the heedless and routine prescription of poultices, in cases of chronic cutaneous inflammation, that some surgeons have discarded them altogether, and, falling into an opposite extreme, have erased from their list of remedies an application which is often very useful, as well as comfortable to the patient.

These observations on the injurious effects of long continued poultices and fomentations to superficial inflammations, apply in a less degree to the instances in which the disease is deeper seated, because the influence is less marked, but it is, nevertheless, equally true, that chronic diseases of joints and glands are sometimes maintained and aggravated, and suppuration induced, by a careless adherence to these relaxing applications.

The stimulants applied for the purpose of strengthening and bracing an inflamed part should be mild, so that they may be frequently repeated. They are often of much service in chronic inflammation of the external tunics of the eye, and you will find a lotion of alum containing one or two grains to each ounce of water generally sufficient at first. Weak solutions of sulphate of zinc or copper may be required after a time, but be careful not to employ them of too great strength so as to produce more than a slight smarting sensation, which passes off in a few seconds, for much injury is done to the delicate textures of the eye, and a most troublesome condition of chronic inflammation, with thickened villous, or even warty state of the conjunctiva is often engendered by the repeated application of strong stimulants, more particularly by the nitrate of silver. The disease thus produced has peculiar characters, which may be generally recognized at once by the experienced surgeon. I do not mean to say that solutions of nitrate of silver and other salts of the same kind are never to be used, but that they are not very often required in chronic inflammations of the eye unattended by ulceration, and I wish more particularly to caution you against their long continued or repeated employment.

There is another mode in which stimulating applications sometimes succeed in curing chronic inflammation, namely, by exciting a more severe inflammation, which seems to eradicate the former disorder, and then itself passes off in the ordinary manner. An attack of erysipelas of the face is often followed by the cessation of an inflammatory affection of the skin or eyes, which had long resisted treatment; and you remember how quickly the ulcers of the leg healed after the occurrence of erysipelas in the two men who lately left the hospital. We sometimes avail ourselves of this hint of nature by applying strong irritants to chronic inflammations of external parts. A blister or sprinkling with savine powder or cantharides will sometimes cure a chronic cutaneous disorder by exciting a smart attack of inflammation. A solution of nitrate of silver or sulphate of copper dropped into the eye once or twice will occasionally bring to a favourable termination an inflammation of the conjunctiva, which has long resisted milder measures; and our journals contain accounts of the cure of obstinate diseases of joints with effusion, having sometimes been obtained by the bold expedient of injecting a solution of iodine into the synovial cavity.

But this heroic method of treatment is, of course, not unattended with danger. The newly excited inflammation may not subside so kindly, and the surgeon then must bear the blame of having aggravated the

disease ; so that the practice of applying strong stimulants to chronic inflammations with the view of exciting acute disease, is not, except in a few safe instances, adopted by educated practitioners. It constitutes one of the great resources of the quack, who is not in the habit of considering the mischief done by his panaceas, and who is not very careful of the limbs or lives of his patients or of his own reputation. That it is sometimes employed by him with success there can be no doubt, and you will do well to take opportunities of acquiring information from the bold experiments of these fearless empirics. An inhabitant of this town had long suffered under that very troublesome complaint,—a chronic inflammation of the Schneiderian membrane, with discharge from the nostrils, disagreeable smell, &c. He had consulted several physicians and surgeons without benefitting by their advice, and had used a variety of mild astringent solutions and powders in vain. One day he happened to be in company with a quack, who discovering his ailment promised him a speedy cure, and gave him a powder to snuff up, telling him to persevere in it for two or three days, in spite of the pain it would occasion. He did so, although a severe attack of inflammation ensued, causing such pain that he thought he should lose his senses, a profuse discharge followed which soon subsided completely, and left him quite well. From that time, now four or five years ago, he has suffered no return of his old complaint. A strong injection thrown into the urethra will sometimes cure a gleet in the same manner, and the ordinary treatment of hydrocele consists in exciting smart inflammation of the tunica vaginalis testis by an injection of port wine, iodine, or other stimulating fluid.

The application of nitrate of silver in substance or strong solution, in some instances proves a very expeditious mode of curing inflammatory affections, particularly certain ulcers of the tongue, os uteri, and cornea, and erratic erysipelas occurring in feeble persons. It is not quite clear in what manner the salt acts to produce these good effects, neither can I tell with any certainty in what cases it should be employed, for I have seen each of the above affections aggravated by its use.

The natural stimulus to the healthy state of the circulatory and nutritive processes is the natural exercise of the function of a part. This is to be permitted when the inflammatory affection has passed away, or when it has nearly subsided. The morbid condition of the hysterical joint is best removed in this way. If the patient cannot be made to exercise the limb herself, it is well to effect passive movements, and if she can be induced to walk about, the weakness of the joint which commonly co-exists with the hysterical pain, and which probably depends upon some slight inflammatory disorder, will soon begin to amend. It is worthy of observation that the joints of the upper extremities, which are in more incessant motion than those of the lower limbs, rarely become the seat of this peculiar disease.

A remarkable illustration of the benefit to be derived from exercising a painful joint in which there are no other very decided evidences of inflammatory disease,

was afforded by the young woman who was admitted into the hospital about four months ago, with her knee bent beyond a right angle and fixed in that position, the slightest attempt to move it causing excruciating pain, so that perseverance in such attempts was out of the question. Gentle pressure also caused severe pain, and she was reported to be kept awake nearly all night and day, by the darting pains in the joint. She had long been confined to her bed, and her suffering and the apparant severity of the disease were so great that amputation had been recommended before her admission, and she was sent to the hospital for that purpose. The absence, however, of proportionate impairment of her health and of the usual physical signs of disease in the joint, together with her ability to bear the weight of the leg in the flexed position of the knee, when she was standing upright upon the other foot, the muscular resistance which was offered to attempts to extend the joint, the absence of pain upon firm pressure when her attention was withdrawn, and the utter futility of all remedial measures which had been employed, combined to lead us to the opinion, that although there might be some slight disease in the joint, it was by no means proportionate to the pain expressed. Having, therefore, subjected her to the influence of chloroform, we extended the limb without much difficulty, and kept it so by splints. No disposition to retraction was evinced. Passive movements of the limb, frictions, &c., were maintained for a time, she was then urged to move about by dint of main force, each day being obliged to do a little more, for if left to herself she never advanced in the slightest degree, though she was evidently most anxious to get well, and was delighted at the improvement. By perseverance in this treatment alone, she gradually regained the use of the limb so as to be able to walk without assistance when she left the hospital. Some obscurity was thrown over this case by the swollen blue cold condition of the limb; and I am by no means prepared to say that there was no disease in the joint, but that it must have been very slight, whereas the pain really experienced was very great.

You will find that it is often no easy matter to decide as to the propriety of permitting or prohibiting the exercise of an inflamed organ. As a general rule it is essential to keep the patient, as well as the part affected, as much at rest as possible during the acute stages of the inflammation. In chronic inflammation it is conducive to the health of the patient that he should be allowed to move about, while we still endeavour to ensure the rest of the organ. In a still later stage, when the inflammation has nearly or completely passed away, and a sense of weakness only remains, dependent upon the structure of the part not having been restored to a natural condition, it is not advisable to maintain these restrictions as to its use quite so strictly. For the exercise of function being the stimulus to healthy nutrition, we can never expect a muscle or joint to resume its healthy condition so long as the movements of a limb are prevented by splints and bandages. At such a period, therefore, it is wise to allow the moderate and cautious use of the part.

Sometimes, indeed, it is necessary to do more, and to stimulate the part to exertion. This is particularly true with regard to the delicate fabric of the nervous system, where a slight degree of inflammation may so spoil the structure as to render it insusceptible of the ordinary impressions. Under such circumstances, if some extra influence be not applied, by exciting the exercise of function to supply the stimulus to nutrition, the texture will still further deteriorate, and a paralysis which might have been cured, by the timely use of strychnia or electricity, will become permanent.

In adopting such treatment, we must not forget that we are dealing with a part recently inflamed, and that a recurrence of the disorder is almost sure to be produced if the stimulus to exercise be commenced too early, or continued too freely. The condition of the part is analogous to that of a patient recovering from illness who requires to be roused to the exertion necessary for health, but who will assuredly lose ground, and perhaps be subjected to a relapse, if his powers be tested too early, or urged too freely.

I suppose that frictions and champooing, which are sometimes so very successfully employed in the treatment of chronic affections of the joints by persons who devote themselves to this occupation, owe their curative effects in some measure to the stimulus and the movements communicated by the rubbing, kneading, and pummelling to which the part is subjected.

With reference to the effect of movement and rest upon a part which is the seat of chronic inflammation, it is to be remarked that the patient generally suffers the greatest uneasiness and stiffness when he begins to move after the rest of the night, and that these wear off when the limb has been in exercise for a short time, though they probably increase again towards night, especially if the limb have been much used during the day. The lame horse shows his defect at the beginning and end of his journey, and the horsemaster knows that to confine him to the stable for a few days would have the effect of disabling him altogether. These facts seem to prove that moderate exercise exerts some influence in restraining chronic inflammation. I grant that it is not easy to turn this hint to a practical account, for it is often difficult to decide whether the tender part will bear the exercise of its function, but it is well not to lose sight of it, and it may modify your directions in some particular cases. I have often observed slight inflammatory affections of joints to be aggravated by too strict an adherence to the rule of keeping them fixed and at rest, and have found them do better, and recover more quickly, when the retentive apparatus has been applied somewhat less accurately, so as to admit a little movement; for instance, when the splints have been discontinued, and strapping and bandage alone employed.

In speaking of the effect of leeches in relieving deep-seated inflammations, I mentioned the sympathetic relation which appears to exist between the internal organs and the superjacent skin. It is in consequence partly of this relation that the integuments of an inflamed joint become red and tender; and it is probable

that impressions are conveyed more readily in the opposite direction,—namely, from the skin to the synovial membrane, so that soothing applications to the former produce a corresponding effect upon the latter; and an irritation of the skin will in like manner be communicated to the joint. This sympathetic relation between the coverings of the body, and the organs placed beneath them, affords, in some measure, a clue to the explanation of the effects of counter-irritants, and furnishes some important practical information as to the principles which should guide us in the employment of these very valuable remedial agents.

If the effect of a blister placed upon the skin of an inflamed joint depends, not according to the commonly received notion upon its drawing the disease from the inflamed part to the skin, but upon the extension to the joint of a slight degree of the same condition which is excited in the skin, we may consider the measure as tantamount to the application of a stimulant to the joint itself, a very mild one, it is true, because its operation is confined to a sympathetic influence conveyed from the skin; it may, therefore, be expected to be beneficial or otherwise, precisely under the same circumstances as would a slight amount of stimulus applied directly to the inflamed part. This accords with what we find to be the general result of experience. When the inflammation of a synovial membrane is acute, the stimulus of a blister on the skin invariably aggravates the disease. It is not till the acute stage has passed away, and slight inflammation alone remains, that the extension of a slight stimulating influence from the integuments can be borne, or is likely to be beneficial.

This view of the *modus operandi* of blisters assists us also in the selection of the spot to which the counter-irritant should be applied, for the radiating influence is felt most strongly in the immediate neighbourhood of the irritant, and we may regulate the effect upon the inflamed part by the distance at which we place the blister upon the neighbouring skin. An inflammation of the eye is sometimes increased by a blister upon the temple, which might have afforded relief had it been placed behind the ear, and it is only in very slight inflammation of the internal tunics of the eye that we can venture into such close quarters with ordinary stimuli, as to apply them to the conjunctiva itself. You probably remarked the request made by the patient who is now in the hospital recovering from a fourth attack of iritis, and who has therefore some pretensions to be a judge of the value of remedies in his own particular case. "Don't you think, Sir," he asked, "that a blister behind the ear would do my eye good now," when I inquired why he wished to have it behind his ear, he replied, "because when it is placed on the temple, it terrifies the eye so much." In the great majority of cases, however, in which it is advisable to apply a blister at all it should be placed immediately over, or as near as convenient to, the inflamed part.

The repeated effect of a succession of blisters is generally productive of more benefit to slight inflammatory affections or the slight remnants of acute inflammations, than one blister kept open by savine

cerate. But when the inflammation has been longer continued and has proceeded to structural alterations, I think that a continued impression upon the skin attended with the discharge of pus is more efficacious. In slight conjunctival inflammations, where a counter-irritant is required, a blister or a succession of blisters will generally answer the purpose; but in cases of chronic cornetitis, where that tunic has been rendered partially opaque, and its surface is roughened and more or less covered with fine red vessels, greater benefit is derived from an open blister, combined perhaps with mild astringent lotions than from a succession of blisters. The same remarks apply also to diseases of joints, where much thickening of the synovial membrane and other structural changes have occurred, and to chronic inflammations of bones with thickening. You have had many opportunities of witnessing the decided benefit which commonly follows the formation of a caustic issue, whereby a portion of integument is killed, and suppuration, granulation, and cicatrization excited, upon a diseased joint in which ulceration of the cartilages forms the prominent feature. These issues should be placed as nearly over the immediate seat of the disease as can conveniently be done, and they are maintained with best effect by the occasional re-application of the caustic potash.

The good effects of counter-irritants are not to be attributed entirely to this communication of a stimulating influence from the surface to the inflamed part, for they act besides, more particularly those which are long continued, such as setons, issues and open blisters, by furnishing a drain to the system, and supplying a new disease in place of the one we are anxious to cure. It appears, in some cases, that local disease, either in consequence of its long continuance or a diseased state of the body, is essential to the general health, and a chronic inflammation will, under such circumstances, resist our efforts to dislodge it, or is driven from one region only to make its appearance in another. This happens more particularly in delicate children, and in persons who have passed the middle period of life, or whose constitution is broken by intemperance, anxiety, hard work, and so forth. The maintenance of a purulent discharge by issue or seton is by far the most effectual local treatment of chronic inflammation in such persons. There is no need to produce a copious discharge, for a slight effect is generally sufficient to answer the purpose. Any little accession of constitutional disturbance will probably vent itself by an increase of inflammation and suppuration at the issue, which becomes a sort of barometer of the health, and should be merely kept open by a pea or thread, and not worried by savine cerate and other irritating applications.

In persons advancing in years, it is rarely safe to allow the issue to heal; but in children and persons in whom the local disease depends upon a disordered state of the constitution, the issue may be closed when the general health has been re-established, or when the child may be supposed to have outgrown the disposition to disease. An issue should not be maintained longer than necessary, for the artificial disease unquestionably

does some injury to the surrounding parts, and unless its presence be required to combat another local affection, or to relieve a particular state of the constitution, the sooner it is closed the better. This is equally true of blisters and other counter-irritants. The inflammation excited by them injures and weakens the limb or joint to which they are applied, and does positive harm unless there be some counteracting good effect resulting from them. Moreover, in young and delicate persons, they are often followed by ulcers and boils in the surrounding skin, which occasion a good deal of trouble. The apprehension of these consequences makes us unwilling to resort to irritating applications, unless they be absolutely required.

Rubefacient liniments, such as the common *Linimentum Terebinthinæ*, or the oil of turpentine itself, which act in the same manner as counter-irritants, and combine the advantages of friction, are often very serviceable in the treatment of slight inflammations of joints. The rapid impression of a mustard poultice renders it exceedingly efficacious in a great number of sudden slight affections, or even occasionally in the preliminary stage of those which, having been preceded by a chill, promise to be more severe; the effects, too, of a mustard poultice pass off so quickly, that they do not entail much evil, even if it does not succeed in arresting the inflammation. An excellent mode of producing instantaneous counter-irritation, which is likely to be very serviceable in sudden seizures of lumbago, sciatica, and other similar affections, is the old plan recently revived, of passing a heated iron quickly over the skin, so as to produce redness, and a smarting or burning sensation. These applications, whose effects are so transient, are not much suited to cases in which disease has been of long continuance, or in which structural changes have occurred.

I do not commonly use the tartarized antimony as a local application, because its effects are not very easily regulated, and I am not aware that it possesses any advantage over other counter-irritants. An issue may be sometimes conveniently established by dressing a small blister from which the cuticle has been removed with *Unguentum Antimonii Tartratis*, and is well adapted to the treatment of some of the severe diseases of joints occurring in children.

Pressure is one of the most effectual means of preventing inflammation, and of checking it when it exists in a slight degree. The lung compressed by serum effused into the pleural cavity is rarely inflamed. A sprained joint is least likely to swell and inflame if it be bandaged at once, and fractured limbs which are enclosed in well adapted splints and bandages soon after the accident certainly swell less, and are less painful, than when subjected to the old fashioned treatment of placing them upon pillows, and applying lotions. The well regulated application of pressure is also one of the best means of preventing the occurrence of injurious inflammation in wounds, and you may often see inflammation of the integuments, and deep-seated structures of a limb, terminating abruptly at the line where a bandage has been applied. This treatment requires to be employed and watched with caution, and

the pressure should be removed if pain increases, for its continuance, when the inflammation proceeds in spite of it, may be productive of disastrous results. I have once or twice known extensive sloughing take place in consequence of inattention to this precaution.*

Pressure is used in a variety of ways in the treatment of chronic inflammation. When the integuments are swollen and purplish, or indurated, in cases of chronic ulcers, in enlargements and indurations of glands, in swellings of joints from synovial disease, attended with thickening of the membrane, or effusion into the joint, pressure, by means of plasters, bandages, or splints, is the most usual and the most effectual means of treatment.

It is not quite clear in what manner it controls the inflammation, or promotes the removal of effused products. Its good effects are not limited to the dispersion of swelling, for it is very beneficial in cases where no swelling exists, such as certain painful affections of joints, attended perhaps with slight crepitation, but unaccompanied by thickening of the synovial membrane, or effusion into the articular cavity.

You have probably remarked, that each of the three methods of local treatment which I have been describing,—stimulants, counter-irritants, and pressure,—are occasionally effectual in arresting the onset of an inflammation, as well as in curing its later or chronic conditions; they are employed before the acute stage has set in, and after its termination, and their good effect at these two periods is confirmatory of what I said respecting the nature of the preliminary stage of inflammation, and the state of the part in which it exists, for it accords with the view I gave you of the enfeebled energies of the organ about to suffer an acute attack of inflammation, that it should be roused to its natural condition, and enabled to break the first link in the chain of disease by remedies of the same nature as those which serve to stimulate and brace it after the storm has burst upon it, and which assist in dispelling the lingering remnants of the attack.

CASES FROM PRIVATE PRACTICE.*

By JOHN RICHARD WARDELL, M.D., Edin.

Late President of the Royal Physical and Hunterian Medical Societies, Assistant Pathologist in the Royal Infirmary, Edinburgh, &c. &c.

SCORBUTUS.

REMARKS.—On reference to the writings of all authors who have described this disease, particular allusion is made to the great prevalence of scurvy in former times—before its nature and treatment were so well understood as they now are. Amidst maritime communities the affection is by far the most common, and our naval history of the last century gives the most appalling details of its ravages, which were sometimes so fearful as to threaten the entire destruction of a

fleet, and often making far greater havoc than the most sanguinary battles. So remotely back as the time of the holy wars, mention is made of the complaint, and it is pretty certain, from various sources of information, that it prevailed in the kingdoms of northern Europe prior to that date. Some of the older writers state its occasional epidemic occurrence in this and other countries; and during some of these visitations many were swept off by the disease. There is one fact now thoroughly substantiated, that of all the alleged conditions entering into the causation of scurvy, diet lacking a proper proportion of acid fruits and succulent vegetables, is immensely the most important—a truth that has been abundantly corroborated by positive and negative proofs. To some of our naval commanders* is justly due the greatest credit for their correct and philosophic observations relative to many important particulars associated with a study of the affection. Being men accustomed to habits of reflection, and exceedingly desirous to banish from their crews so destructive an assailant, they carefully watched its progress and decline, tried different remedies, and endeavoured to trace to its true cause the rapid recession which it would make when the ship reached a distant port, and the diet of the men thus became changed; it was in this manner that the wonderful virtue of the acescent fruits and fresh vegetables was unequivocally established. Military medical, and other records† also furnish us with instances of its calamitous occurrence amongst the troops; and these have generally occurred after the men had been debilitated by long and laborious campaigns, and when so circumstanced as to be unable to procure the proper amount and right kind of provisions. Fodéré tells us that the soldiers in the army of the Alps suffered by it very severely, and Larry remarks the prevalence of scurvy during the siege of Alexandria. The reports, which during the last ten or twelve years have been given to Government authorities, relative to our prisons, gaols, and hospitals, have attested the fact that error in kind, or insufficient quantity, of diet constitute the most fertile of all causes in the production of scurvy. The general failure of the potato crop two or three years ago, undoubtedly gave rise to the unusual prevalence of the complaint in question—a position which those who saw much of the mode of living amongst the poor, the immensity of their destitution, and the general distress which the loss of this valuable article of food gave rise to amongst them, can indubitably attest. Turning from these general observations respecting the disease, and confining these brief remarks more particularly to the case now given, it will appear manifest that causes brought into operation in a solitary case, from a combination of circumstances of a nature similar to those

* Cook, Parry, Berkeley, Bridport, Hawkins, etc.

† Larry. *Thém. de Chr. Militaire*; *Hist. de Louis ix.*, par le Sieur Joinville; Hume, Lingard, Alison, etc.

where this influence extends to numbers, were followed by like results; and, as the sequel will show, such clearly consisted in an improper and scanty food. The patient having long laboured under dyspepsia, had for that complaint sought the opinions of various practitioners, and the last under whose care he was previous to my being called in, strongly recommended one description of diet, which, as he fallaciously conceived, was indicated until the digestive organs had fully regained their tone. As stated in the report, for two years the individual had lived chiefly upon stale bread and tea, and when I first saw him, his stomach had become so debilitated that most other kinds of food could not be taken without producing distension and disorder; if he ate a full meal it was sure to render him very unwell. I may here mention, that amongst the lower classes of society, there is a description of dyspepsia produced by individuals living so much upon slops, which their straitened circumstances compel them to do, and which those practitioners who have had much communication with the poor cannot fail to have noticed. Amongst many of the lower orders, tea and cake form the staple articles of diet; and these persons, when they apply at the hospitals and dispensaries, complain of watery eructations, flatulence, gastric distension, and cardialgia; the pulse is soft and resistless; bowels torpid; and frequently there is flabbiness of the muscles, with more or less of general emaciation; and the patient upon being interrogated, will often say that any other kind of food produces pain in the stomach and much uneasiness. I recollect that my friend Dr. Hughes Bennett, now Professor of Physiology in the University of Edinburgh, first pointed out this fact particularly to my attention. That gentleman also told me that he had not long before attended a case very illustrative of this position. A young lady who resided (if I recollect rightly) at Montrose, came to Edinburgh to obtain advice for a stomach disorder, under which she had long suffered, and placed herself under the care of Dr. Bennett. On being interrogated, she asserted that tea and bread were the only articles of food she could take. She was weak and emaciated; had become nervous and irritable; the bowels were disordered; and she complained of flatulence and cardialgia. Dr. Bennett very properly prescribed mild tonics, ordered her to take no more tea, and to have a varied and animal diet, under which she rapidly recovered.* Those practitioners who reside in rural districts, and who may chance to peruse these remarks, will bear me out in the foregoing statements, that amongst the labouring poor, the

disease in question is very frequently met with; and so far as my own experience warrants me in giving an opinion, restriction as to the quantity of warm liquids, the daily allowance of fresh animal food, and ten or twenty drop doses of the diluted sulphuric acid, in a weak infusion of calumba, or in water, is a very successful mode of treatment. Considerable quantities of diluent liquids cannot fail to impair the digestive organs; first, by diluting too greatly the gastric juice, and thus preventing that reductive action upon the food, so necessary in this, the first stage of digestion; the parietes of the stomach become morbidly distended by the evolution of gases; the contents of the organ are propelled, insufficiently acted upon, into the duodenum and lower parts of the alimentary canal, and the conversion of the ill-formed chyme into chyle is imperfectly performed; the bowels become disordered from the passage of indigested matters; hence diarrhoea or constipation, caused by irritative action on the digested surface, or the collection of crude matters. The circulation being in a secondary manner rendered slower, the liver becomes engorged, and disorder of the biliary apparatus is superadded to the morbid conditions already existent; and so it is, that whenever there is chronic dyspepsia, the practitioner may rest assured that the functions of the hepatic viscus are more or less at fault.*

It has been said that the patient whose case is now particularly considered, lived, during two years, mainly upon one kind of food, under which those symptoms that could not fail to follow succeeded, and scorbutus was the result. When I first saw him, the bodily powers were much reduced; the eye looked dull and listless; lips blanched; cheeks fallen; gums mottled and vascular; teeth loosened; extremities swollen; petechiæ, and dark hæmorrhagic patches, were also manifest, and it was too obvious that unless some amendment was ere long produced, a fatal termination would ensue.

Between purpura hæmorrhagica and scorbutus,† there is an essential difference, notwithstanding some nosologists having considered them identical; and this difference appears indisputable, from the following considerations:—Because scurvy comes on at certain periods, at least, whenever it is considerably prevalent during particular seasons; scurvy comes on gradually; purpura

* For information on this subject the reader is referred to Dr. Wilson Philip's excellent treatise on "Indigestion."

† The late Dr. Graham, of Edinburgh, once observed to me, that his experience impressed him with the opinion, that intemperate butchers, those who were hired by the master-butchers as slaughterers and assistants, were particularly prone to purpura hæmorrhagica. This class of individuals in Edinburgh is almost invariably addicted to drinking large quantities of ardent spirits, and lives chiefly on animal food. During the time of my being Clinical Clerk in the Royal Infirmary of that city, some instances confirmative of the Professor's opinion, are now distinctly remembered. Was this condition owing to too much nitrogen being taken into the system?

* I distinctly recollect that Dr. Christison, in his Lectures on Dietetics, gave it as his opinion, that in convalescents from fever, and other patients, where much general debility was present, and where the individuals asserted they could not digest soups, that small quantities of well-cooked mutton could not only be taken with impunity but benefit; and my own observations have confirmed this remark.

often quickly; in the one, spongy gums invariably are seen; in the other this is not the case. In scorbutus, acid fruits and succulent vegetables will alone produce a cure; in purpura they are taken without effect. In the one, blood-letting is often of great service; in the other, it would be followed by considerable aggravation of the symptoms; hence, from these facts it cannot be said that they are really the same, although admitting of many similarities.

The study of those morbid conditions in the system which give rise to scurvy renders them of deep interest to the scientific pathologist,—to him who examines the causes as well as the effects, because its study shews him that a primary change in the blood will readily affect the entire system, and produce morbid anatomical conditions of the gravest character; and, indeed, a reflection on these changes inclines us to think with less prejudice on those humoral doctrines with which the minds of the older physicians were so much imbued. Some writers have affirmed that scurvy was dependant upon capillary distension; but experiments have tended to an opposite opinion, because, when a limb has been injected, the extravasation, if any, that has been produced, was not discernible to the naked eye, either in the integuments or in the sub-cutaneous cellular tissue, or between the muscles. If it were

dependant upon capillary parietal distension, it would not be too hypothetical to presume that the nervous system was the primary seat of the disorder, because the nervous fibrillæ which supply the extreme vessels with nervous energy, improperly performing their functions, the vascular extremities acquire a tonic fulness—a fact that has long been established by positive and negative proofs. For instance, in fever the capillary system sympathises with those changes which are produced in the great nervous centres,—a doctrine propounded by Hoffman, and established by Cullen. Again, in those cases of apoplexy described by Abercrombie as *nervous apoplexy*,* the extreme vessels are affected, but in a manner opposite to that which they are during the febrile paroxysm; the brain, from a diminution of nervous power in itself, fails to transmit the requisite nervous energy to the fibrillæ; the walls of the capillaries are morbidly resistless, and transudation of the aqueous particles of their contents takes place, and thus occurs that not uncommon symptom of copious perspiration. From a consideration of these facts, we cannot refer the true cause of scurvy to disease in the capillaries themselves. That the blood is in a vitiated condition, and that the other phenomena are entirely dependant upon its morbid changes, certain considerations tend to prove. In all the

* A few days ago I was hastily summoned in consultation to a case of what I considered a good example of the above description of disease. The individual was a gentleman, between 60 and 70 years of age, stout and muscular, and had been paralytic a year previously; for, remarkable to say, exactly twelve months from that day he was struck down in apoplexy, which left paraplegia of the left side. This gentleman throughout life had been a man of active business habits, and constantly engaged in large monetary transactions. Having acquired a handsome fortune, he retired into private life, soon after which he had the first fit, but after that attack he so far recovered that he had determined to resume his former calling, the monotony of retirement being felt so irksome. About eleven o'clock in the morning he was found lying on the dining-room floor, in what was conceived to be a dying state. A few minutes previously he had been seen by some of the inmates, and was then, to all appearance, in wonted health. On my arrival he was in bed; the general practitioner who had first been called, and who had been in attendance half an hour, had bled him to twelve ounces. The pulse was of large volume, and quick; the pupils contracted; much convulsive action of the muscular system; the head not very hot; the face, neck, and chest, cool, and bedewed with a copious perspiration. The gentleman in attendance very properly said, that although the pulse felt as if it were a bleeding pulse, yet further abstraction was the question. I did not hesitate, after even a cursory review of the symptoms, to give it as my opinion, that no more blood should be drawn, but in preference recommended powerful counter-irritants. Sinapisms were quickly applied to the thighs, calves of the legs, the nape of the neck, and along the whole course of the spine, with hot bottles to the feet. An injection, with an ounce of turpentine, and two drachms of the compound spirit of ammonia, in half a cupful of starch-gruel, was quickly administered, but only for a moment retained, as the sphincter was quite relaxed. Soon after the mustard plasters were applied, the unwelcome symptoms began to disappear, the pupils became larger, breathing more natural, countenance improved, and pulse softer. As the bowels had not been moved, it was agreed to administer an enema similar to the

last, but in a quart of gruel, which was retained. In the course of a couple of hours he was so greatly improved, as to be considered out of danger. Now, in this instance, I have little hesitation in thinking, that if the surgeon had allowed the blood to flow until he had "thoroughly lowered the pulse," the symptoms would have become more formidable, or perhaps the patient would have rapidly sunk, because, as observed in the text, this I considered to be of that description of apoplexy in which there is considerable prostration of the nervous system, as evinced by the copious perspiration. In a stout, broad-chested individual like this gentleman, it was desirable to relieve the congested lungs and the overloaded heart, but in so doing the greatest caution was requisite, seeing that Scylla and Charybdis were on either side. I recollect some few years ago being called to an elderly female who was struck down in her third apoplectic seizure; the pulse was strong and quick; she perspired very freely. Being alone guided by the pulse, I determined to bleed; scarcely had four ounces been taken, when the pulse suddenly became smaller, and in a few moments the patient expired. It could not possibly be said, that she would have recovered if she had not been bled, yet I am ready to admit, that it would have been better had the lancet not been employed, and the recollection of that case will always make me think carefully before blood-letting is had recourse to, where there is much sweating. I have mentioned the latter instance because I always reflect upon it as an error in treatment, and in the hope that it may warn others, when called to instances of a similar nature. In medicine, however paradoxical it may seem, the most valuable lessons of practice are not always gained from what has been done right, but from what has been done wrong; and it would be profitable often if we knew the mischances as well as the lucky hits of those who write on and practice our too frequently doubtful art.

a The supervention of powerful diaphoresis as critical in continued fever, is ever to be regarded as a most unwelcome symptom, because it shews the great debility of the nervous centres. From a more extensive consideration relative to the pathological fact in question, the reader is referred to a series of papers on Fever, which the *Medical Gazette* did me the honour of publishing in the years 1846-7.

post-mortem appearances which I can find given of this disease, paleness of the tissues is particularly mentioned, consequent, of course, upon diminution of red particles; and as physiologists have unequivocally exemplified, that the vivifying influence resides in these particles, their diminution must give rise to diseased conditions of a more manifest and general character. These red particles are in an occult manner derived from the materials produced by digestion, and require certain constituents; but if the ingesta are such as not to yield the requisite constituents in due quantity, the elaboration of the particles must needs be imperfect, and the portion given off unequal to the imperative demands of the system; hence the loss of vivifying power, and the conditions which constitute disease. Acid juices and succulent vegetables, by possessing these elements, promote the cure. In scurvy, the occurrence of syncope is one of its symptoms; now, in anemia and chlorosis the same occurs, and in the latter, we know that the red globules are sometimes diminished to even one-fourth of their normal quantity, and in such instances syncope is a common symptom; hence, from similar causes similar effects. The first indication of scurvy is a tawny dulness of the skin, manifestly proving that the blood is primarily diseased, and that to its lesion we must refer its true pathology.

It being conceded that the blood is in a morbid state, the next question which may be asked is,—how are the petechiæ, vibices, and hæmorrhagic patches produced? It is a physiological fact, and one that has long ago been pointed out by Le Gallois, and other philosophic enquirers, that the action of the capillaries is imperfectly carried on unless they receive a stimulus from their contents, and this stimulus can alone be properly produced from healthy arterial blood, therefore, when their stimulus is diminished their functions become impaired, and congestion and extravasation result.

On reference to the above case it is seen there was œdema of the inferior extremities, with indurated thickening of the integuments* at the flexures of the knees, conditions almost invariably present in true instances of this disease. These morbid depositions are by far most common in the inferior extremities, in the sub-cutaneous cellular tissue, and between the muscles, and are in some measure dependant upon

gravity. From whatever cause debility of the circulatory function is produced, swelling of the legs is a most probable result, dependant chiefly upon gravity; but in this disease there is a morbid state of the blood itself, as spoken of above, which must considerably favour such result. In those cases in which there is a rapid circulation, fibrinous effusions are more common than when the pulse is slow.*

The constant relaxed state of the bowels, and the light-coloured stools, in the instance of this man, are symptoms highly indicative of the complaint. As he improved the evacuations became more natural.

Soon after my attendance on this person, other cases of scurvy came under my observation, but these were of the milder form of the disease, and being treated at an early stage, were soon, under ordinary remedies, restored to health. The cases referred to were confined to the lower orders, and attributed to the scarcity of potatoes, upon which the poor are so dependant as a chief article of food. It having previously been pretty clearly shown that the loss of this vegetable gave rise to the unwonted prevalence of the disease, I will not here enter upon a question which Einhoff, Vauquelin, and others, have from their chemical researches satisfactorily explained; but I may add, that in those cases which I saw, the individuals for months before had been unable to procure the potato as an article of diet.

In the conclusion of those cases which during the last three months have appeared in the pages of this Journal, I must offer some apology for the length to which the subjoined remarks have inadvertently extended, yet, as the imperfect observations that have appeared inclined to practical results, it is trusted they have not been wholly unprofitable to those who might chance to read them. Being such examples of disease as from time to time are met with in provincial practice, it is not to be expected that they would be of that rare description which the medical officers of metropolitan institutions can cull from their case-books; it would, however, afford me much delight if their publication in any degree tended to induce some of the numerous well-informed members of our profession which there are now to be found in all the remotest districts of the country, to record those instructive illustrations of disease which frequently come beneath their notice. There was a period in the history of our profession when medical literature, unless it emanated from schools and colleges, had the qualifying recommendation of springing from the too-often erroneously conceived fertile brains of metropolitan

* Some chemical pathologists have affirmed that there is positively an abnormal increase of fibrin in the blood of scurvy patients—a statement, unless well authenticated, that appears doubtful, because, although the coagulability is not destroyed, it is certainly less than in healthy blood; while the solution of continuity in the cicatrices of old ulcers, argues powerfully that the plastic properties of the fluid are diminished. Those who have propounded the doctrine of excess of fibrin, base their opinions in some measure upon the circumstance of abnormal organized depositions being common in various parts; but the languor of capillary circulation,—the capillaries rupture, as explained in the text,—together with the effects of gravity, seem sufficiently to account for the morbid anatomical characters in question.

* Some physiologists have denied that the *vis-a-tergo* has any influence whatever on the extreme vessels; this fact alone is rather at variance with such doctrine,—or is it merely from the greater transit of fluid, that more particles are extravasated,—and not from the *force* with which the blood is propelled.

big-wigs,—was held in but slight estimation, as if the phenomena of disease could alone be accurately studied in the halls of a hospital, and opinions and practice alone with safety received through the *ipsi dicunt* of lucky professional dignitaries, or, it might be, courtier or *divinely created* physicians. Let those who question the position maintained refer but to the numerous talented productions that so frequently appear from provincial practitioners, and they will at once be convinced that the abilities of these authors are not mediocral—that they have an indefeasible right to “say their say,” and that their opinions and doctrines should be canvassed with respect. Not long ago, one of the judges at a medical trial very correctly observed, that scarcely any town in the provinces was without its Brodie or its Locock,—that is, if circumstances for observation, and the chances of gaining the ascendant, had been offered to them, as they have been to the names referred to. It is true that there are advantages in the three capitals which afford greater facilities for prosecuting professional enquiries, and obtaining professional eminence, which provincial towns do not afford; yet it is within the power of every man, if he chuses, however disadvantageously situated, to achieve much more than he would at first have conceived practicable. Every one setting himself up as a practitioner of the “healing art,” virtually enters into a moral compact with his patients; and he who does not avail himself of those sources of information placed within his reach, is nothing less than a moral delinquent. No man has a right to conceive, that going forth armed with his diploma, he is henceforth the sure and competent practitioner,—that the study of his profession has terminated, for it might more truly be said, that it has then but really begun; and he who ceases to be the student, should cease to be the practitioner also. Every day’s experience must convince the medical man that the progressive enlightenment of the public must render them less easily made the dupes of chicanery and mysticism than they once were, and that boasted nostrums and secret remedies, are regarded, and rightly, with suspicion. The system of “elegant draughts,” and “nice comforting cordials,” given with little reference to the fundamental causes of the complaint, is fast exploding, and the well-educated are no longer to be the victims of such gullability; they have learnt, however, more correctly, to recognize the man of scientific acquirements—him who exercises what Armstrong termed the *genius* required for medicine—reflection; and the assuming boasters must, ere long, give way to their well-informed and thinking competitors. Routine systems, and conventional notions, are becoming tested by their claims to truth, and accepted according to rational deductions. The indefatigable labours of many of those who cultivate the science of medicine in that spirit of energy and zeal in which alone it can conscientiously be followed, are

every day shedding new lights upon what was once obscure; they are trying, through experiment and ratiocination, to account for anomalies, and, as far as possible, render the science an exact one,—to bring treatment more successfully to bear upon disease,—to attack causes instead of the effects of causes—symptoms; and render more potent an art, of all others, of the greatest concern to humanity. All then are bound, so far as it lies in their power, to lend their aid in carrying out such laudable changes, and every new fact established will add another stone to the fabric of truth and certitude, which is gradually rising beyond the levels of prejudice, and above the wrecks of error. Those mistakes into which we sometimes fall, might often have been averted by more careful examination and patient reflection; and an error in diagnosis is not unfrequently attributable to a hurried review of those phenomena that are thrown out in boldest relief, and more likely to impress the mind.

At a future period it is my intention to endeavour to show, that many medical men do not sufficiently cultivate the *faculty of perception*, by which alone we can decide on those nice distinctions, when even opposite conditions are simulated, and when this or that way of thinking would involve important results; this, with some other considerations suggestive of improvement in the manner whereby medical knowledge would appear to be more correctly pursued, I hope more fully hereafter to dilate upon, and will be contented here with a mere advertance to the fact. As sometimes grave causes can only be distinguished from partially-developed and intricate appearances, it is essential that we should cultivate the powers of detecting these to their fullest indications, and with the greatest certainty.

In some of the foregoing cases, as it will be recollected on their perusal, there was much room for diversity of opinion, and in some instances the treatment was based upon a correct solution of conditions, that, when cursorily reviewed, would seem problematical; and if certain considerations there mentioned were recounted, it would be manifest that it is of weighty import to remember states in the progress of diseases, which must be seen, and cannot accurately be described. To pursue these and many kindred considerations, would here be out of place, but it must be conceded that, although medical science has of late years made gigantic strides, yet until the true spirit of independent enquiry becomes more diffused, and all will study as well as profess their art, there will be fallacies existing, and erroneous opinions maintained.

27, Acacia Road, Regent’s Park.

CASE OF ULCERATED STOMACH.

By GEORGE WALDRON, Esq., Surgeon, Bath.

I was sent for early in the morning of November 12th, 1848, to visit a Miss E., 37 years of age, of a dark and sallow complexion. I found her labouring under severe and violent pains in the epigastrium, accompanied with cramps of the extremities, a sharp and vibrating pulse, of little volume, and the body suffused with cold and clammy perspiration. Being informed that she had taken a pill late on the preceding night, and that to the effect of this pill she mainly ascribed her present sufferings and condition, I desired to see the prescription, and found it to contain,—Extr. Aloes, Extr. Rhei utr., gr. xij.; Extr. Nucis Vomice, gr. vj., in pil. xij. dividend. Capt. j. vel. ij., hora somni, alternis noctibus.

I directed a draught, with sulphuric ether and laudanum, to be immediately administered, and requested Mr. Taylor, my partner, to see Miss E. within the lapse of a few hours, and he then made the following note:—

Quarter-past 12 o'clock p.m. Saw Miss E., who still complains of great pain in the epigastric region; is unable to lie down, and has experienced no relief from the medicine prescribed by Mr. Waldron, this morning at seven o'clock; her countenance is contracted and anxious; she attributes to the pill taken at twelve o'clock on the preceding night the increase of pain, and believes it to be the cause of her present illness; pulse now imperceptible, with cramps in the extremities; cold and clammy perspiration; tongue dry and rugged; great thirst, and prostration of strength. Ordered, in conjunction with Mr. Waldron, Morphine Acetat, gr. ij.; Hydrarg. Chlorid., gr. xij.; Cons. q.s., ut fiant pil. vj. Capt. j., tertiis horis, in conjunction with an effervescing mixture. A mustard plaster to be applied over the region of the stomach for twenty-five to thirty minutes.

At 6 o'clock p.m. Miss E. expired, whilst taking a cup of tea.

Autopsy.—The body was spare and emaciated; on opening the abdomen the intestines bore marks of high inflammation, flakes of coagulable lymph were thrown out, and the intestines were everywhere united with their peritoneal covering; in the centre of the stomach, immediately between the greater and lesser curvature on the lower side, an ulcer, about the size of a shilling, was found, with indurated and thickened edges, and of dense and scirrhous hardness; on removing the stomach from the body, a second ulcer was discovered, completely agglutinated with the pancreas and peritoneal covering, and which it would appear guarded the second ulcer from giving way. A large quantity of fluid was found extravasated into the abdomen.

Observations.—As the case at the time excited some interest, it was in every respect well, that a *post-mortem* examination did take place. The suddenness of Miss E.'s death, the nature of the medicine she had taken late on the preceding night, and the impression on her mind and also that of her relatives, that this medicine was the cause of her death and sufferings, rendered the examination imperative. The *modus operandi* of such a combination, on an ulcerated surface, cannot

easily be calculated upon, and one would not desire to hazard an opinion; all that can be said is this,—that Miss E. took a pill of this character, and that next day she died. The examination of the stomach further shewed, that had she not taken the pill her term of days was numbered. Still the violent exacerbation of pain, &c., on the night after the pill was taken, might, and ought to lead medical men to the serious consideration,—how far such a combination of medicine was calculated to do good or harm in such a case, and so far prove beneficial to medical science.

MENTAL INFLUENCE OF THE MOTHER ON THE CHILD

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND
SURGICAL JOURNAL.

SIR,

The mental influence of the mother on the fœtus was fully believed in the olden times, though discredited by medical philosophers of the present day; but general rules may admit of exceptions, and the occasional asserted instances of transmission to the child of maternal mental impressions, which come under the notice of medical practitioners, might be worth some investigation, though almost invariably shunned from the dread of the imputation of credulity or scientific heresy.

The case which I am about to mention certainly presents the semblance of a result of maternal mental influence rather than that of coincidence, and as I can vouch for the facts, they may perhaps be deemed worthy of record.

On the 24th of last October I attended Mrs. A. in her confinement with her fourth child. The labour was natural, and she gave birth to a fine boy, who, on examination was found to suffer severely from hare-lip and cleft palate towards the left side of the mesian line. The former children were perfect. Mrs. B., who I then considered fully six months advanced in pregnancy, saw the child from motives of curiosity. She informed me that she experienced no feeling of alarm, though somewhat surprised at the morbid appearance. I believe she saw the child accidentally on two or three subsequent occasions.

On the night of February the 1st, she herself gave birth to a very fine healthy female infant, quite perfect, but from the septum of the nose extending downwards to the left of the mesian line, and through the thickness of the labial convexity, the outline of a hare-lip was perfectly distinct; on and near the nasal septum small clots of varicose capillaries formed the apex of the figure, the outline then continuing downward with dark lines, and through the thickness of the labial margin a livid hue distinguishes the marked surface from the normal structure. The hard and soft palate are perfect and natural. The child is now a fortnight old, and the mark has faded considerably, and I hope will not disfigure it hereafter. If we are to recognize

cause and effect in this occurrence, it will be interesting to bear in mind the period of pregnancy at which the impression was made. Admitting a nervous connection between the mother and the fetus, that connection would doubtless become stronger after the middle of pregnancy, if indeed it may not be supposed first to date from thence—viz., the period of quickening, when the fetus is first endowed with motor power. In other cases of supposed maternal mental influence which have come within my notice, the impression has occurred subsequently to the period of quickening. This I should be inclined to anticipate. At the earlier periods of utero-gestation, while the fetus is as it were parasitically connected with the mother, its existence is most precarious, and its destruction is very apt to ensue from any severe maternal shock; but at the later periods, the being of the fetus is more certain and independent, and then probably it is, that the vital stimulus is transmitted by a nervous channel as well as in mere connection with the sanguineous current. If we allow the occasional occurrence of maternal mental influence on the fetus, it would also be a matter of curious speculation as to the circumstances under which it is liable to occur. I do not believe it to be always ascribable to violent mental influence: in the present instance such was not the case, and the mother is a very sensible woman, of lively and cheerful disposition, but not of very excitable and imaginative temperament; there was merely the visual impression combined with some degree of curiosity and surprise.

I am Sir, your obedient servant,

BUTLER LANE, M.D.

Ewell, Surrey, Feb. 12, 1848.

ON MESMERISM.

By HENRY DAYMAN, Esq., Surgeon.

It was the trite observation of a great painter,* that "the history of errors, properly managed, often shortens the road to truth." Now, although it may be impossible to manage properly a history of the errors committed in the healing art, because "*difficile est proprie communia dicere*," still we are not without excellent charts to guide our *Materia Medica* among the mysterious quicksands, which, in the shape of idiosyncrasies, prejudices, fantasies, and other difficulties, surround the life of man,—charts laid down by the learned and the good, in all ages, for the use of their children, and the behoof of mankind.

Grave men and honest have witnessed the wonders of mesmerism, and have borne testimony to the truth of what they have seen; this paper, therefore, will not be found attempting in any way to controvert the evidence of other men's senses; but, as the *whole* truth has not always appeared, I have thought it expedient, after some observation, to lay before the profession certain phases of the mesmeric treatment which hitherto have been but little considered.

It is not many years since the powers of iodine over glandular disease began to be developed, and numerous and lofty were the conjectures of physicians on the influence which such a medicine would hold in the republic of physic. At last some keen and close observers began to discover that this deep-searching agent, not content with removing diseased structure, would occasionally carry off the very normal tissue, and then it was deemed right to warn the profession of such possible contingencies. Thus have we heard, throughout the length and breadth of the land, the all-powerful virtues of mesmerism set forth; but medical men have not had timely warning, as in the case of iodine, of the dangers which may attend the indiscriminate use of this power.

The following sketches will, I hope, sufficiently illustrate my meaning:—

CASE 1.—A lady, subject to occasional attacks of turbulent action of the heart, out of mere curiosity, suffered herself to be mesmerised. Within a few minutes all the most frightful symptoms of angina pectoris began to show themselves, and it was with difficulty, and not until many hours had elapsed, that the circulation was brought back to tranquillity. The mesmeriser was an amateur, and altogether unacquainted with the principles of medicine.

CASE 2.—A girl, half-idiotic, yet of sufficient understanding to earn her own bread, was found to be a suitable subject for mesmeric exhibitions, from the facility with which she received the necessary impression, and her easy transit into a state of coma. After submitting to the ordeal for some months, she was discovered to have become *entirely* devoid of intellect, so that being deprived of all means of gaining a livelihood, or even of performing the most ordinary personal duties for herself, she now exists, a burden to her parish, and an object of distress to those about her.

CASE 3.—A young woman, of florid habit, and irritable temperament, about 25 years of age, was attacked by epilepsy, for which she consulted an eminent person. The treatment at first was of the most approved kind, for the doctor brought all the artillery of a very powerful mind to bear on the case. No remedies, however, succeeded in preventing the recurrence of the fits, and she was at last advised to try mesmerism.

Two years after this I saw her, when she informed me that the mesmeriser had "cured her fits," but, to use her own emphatic words, she was "a wretched woman." The epileptic paroxysm, which had habitually returned about every fortnight, ceased to appear, but in the place of this periodical outbreak, a pitiable wreck of nervous energy had taken possession of her, and both the mental and physical economy were laid prostrate, so that she constantly felt and declared, that the greatest boon which could befall her would be the restoration of the epilepsy.

The foregoing cases have been selected as specimens of mesmeric results, as they appeared under three different aspects; and I have no doubt that all medical men who have seen the mode of treatment in full exercise, and have studied, without let or hinderance,

* Sir Joshua Reynolds.

the evil and the good of the system, will recognize in these sketches truths with which they are familiar, however feeble the delineation here given.

The first case may be taken as the type of a numerous family of patients, on whom slight disturbances produce very serious results, and with whom, therefore, cautious men are not prone to meddle unnecessarily. It may, however, be urged, that the somatic manipulation was not carried far enough in this case, and that as the treatment proceeded, the primary symptoms would have subsided. On this head I would only refer to the opinion of an able psychologist,* who says, in speaking of the employment of animal magnetism, as a means to produce re-action in the nervous system, "This procedure demands great caution and individual discrimination, since, after all, it is only proceeding by guess. The physician may here be compared to one attacking the case with a stick. If he strike the disorder, so much the better; if he strike the patient, so much the worse. The question always is, how far may a psycho-physical exaltation go, in this or that individual patient, in order to produce only a *salutary* excitement, and where is the point at which this excitement may become *dangerous*? It never can be a matter of indifference: he, therefore, who will venture to give a decided answer to this question, as applied to the case which he is treating, may likewise venture on this procedure."

The second case presents a terrible picture of innocent martyrdom, on which it would be painful, and of no advantage, in this place, further to dilate.

The third case, perhaps, offers more interesting features to the consideration of the physician. Here, it is evident, it would have been better to have borne the actual ills, than to have sought unto the possible but questionable cure. The epileptic diathesis existed in the constitution, like the wolf-note on the piano, well known to musicians, and it would have been well, had both discords been equally capable of bearing the same treatment. In the latter, the judicious tuner distributes the note over the whole instrument, and the flaw is lost in the general harmony. Not so the mesmeric tuner, in the instance before us, for, although the diffusion of the epileptic discord was accomplished, the effect was the reverse of harmonious. It appeared as if some subtle spirit was habitually condensed in the body, and that the issue of this process was a periodical epilepsy, exhibiting, in some measure, a *vis medicatrix* analogous to that which is seen in the struggles of ague to throw off the poison of disease. Howbeit, the condition of the patient, after the "cure," was far worse than that in which the treatment had first found her. In the place of the epilepsy, the body was governed by what may be termed a *psycho-neurosis*, and the fear was upon all who saw the case, that such a state of things might lead, as Eschenmayer (himself an enthusiastic mesmerist,) has suggested, to some peculiar form of lunacy.

Such are a few among the *caveats* which may be entered against this popular therapeia. Hitherto

science has taken little cognizance of its merits: yet, "Thus much appears from the evidence examined, that what is called *idio-magnetism* is not a more exalted, but a more fettered state of the mind, in which it is subject to the will of other men,—to the sway of its own instinct and of fancy—nay, even to the influence of mineral and telluric forces. That this condition must be considered as *pathological*, cannot, therefore, be doubted."* It must, however, be confessed, that to regard the series of mesmeric phenomena as a state of morbid "transition," does not assist the physician in assigning to it a place in the healing art. To oppose one disease to another has been the legitimate province of *Allopathic* science from the days of "eldest time;" and some of the warmest advocates of mesmerism have, it is conjectured with this view, sought to engraft their doctrines on catholic medicine. Yet, whether, on investigating more strictly all the powers and results of animal magnetism, "*simile simili gaudet*," will not be found to be the more appropriate motto of the school, is at present an open question. Should the decision of future inquirers give this place to mesmerism, it is obvious that it would eventually become the handmaid of homeopathy.

I leave to others the purely psychical field to which a further consideration of this subject might lead. It has ever been the wisdom of the true metaphysician to look but in one direction for the light. Let us, then, who are both physiologists and metaphysicians, keep this truth steadily before our eyes in our profound reasonings on the material world. "*Physica sunt opaca, non lucem sed lucidas res videmus*."

Millbrook, Southampton.

CLINICAL NOTES FROM PRIVATE PRACTICE.

By W. H. RANKING, M.D., (Cantab.) Norwich.

REMARKABLE SPASMODIC AFFECTION OF THE MUSCLES SUPPLIED BY THE PORTIO DURA.

A lady, aged 65, residing in the marshy district, near Lynn, came recently to this city to take my opinion on an affection which had caused her very great distress, although not accompanied by any severe amount of pain. Her health had been generally good until twelve months back, when she became the subject of pain in the limbs, apparently of rheumatic origin. About the same time she first noticed the commencement of the affection for which she sought my advice, and which consists of a peculiar spasmodic twitching of all the superficial muscles in the left side of the face. This originated in the left genio-hyoid muscle, but had now engaged the orbicularis, the levator angulæ oris, the zygomatics, and in fact every muscle supplied by the portio dura, on the left side, and shewed a disposition to extend to the other side. The twitchings occurred at intervals of about one minute, and lasted during twenty or thirty seconds, so that there was scarcely any abatement during the day, and these

* Baron Von Feuchtersleben's *Psychology*. Sydenham Society's edition, p. 338.

* Op. cit., p. 209.

twitchings were so violent that articulation was impeded, and the patient was constrained to apply her hand to the cheek to restrain its motions. There was at the same time considerable lachrymation, but no pain, beyond a feeling of dragging from the abnormal muscular action.

I examined the patient carefully to discover some explanation of this unusual symptom, but could find none. There was occasional pain in the head and giddiness, but not more than is seen in ordinary gastro-hepatic derangement. There were no symptoms of paralysis, nor any affection of the special senses. I made out particularly that she had no noises or imperfection of hearing, and had never suffered from otorrhœa. The appetite was good, bowels regular, and in fact but for her distressing nervous affection, she would have considered herself well.

I ordered her quinine and steel, with belladonna frictions in front of the meatus auditorius, but have not heard the result.

I am induced to place this case on record from the belief that it is an affection of very unusual occurrence. I have consulted such works of reference as are at my disposal, but can find only one similar case, which Dr. Graves has narrated, ("Clinical Medicine," 2nd Ed., Vol. i., p. 571,) as an instance of a disease hitherto undescribed. His case was also that of a female, past the meridian of life, but it appears to have been of longer duration, and had invaded both sides of the face, as it seemed disposed to do in the present case. No account of the treatment or progress of the affection is recorded, nor is any explanation of the phenomena attempted.

Hospital Reports.

QUEEN'S HOSPITAL, BIRMINGHAM.

CLINICAL REPORTS OF SURGICAL CASES UNDER THE TREATMENT OF PROFESSOR SANDS COX, F.R.S., SENIOR SURGEON TO THE HOSPITAL.

Reported by PETER HINCKES BIRD, late Resident Medical Officer.

CASE XV.

CANCER OF THE SCROTUM.

John Clark, aged 47, a sweep, was admitted into the Queen's Hospital, October 24th, 1846, under the care of Professor Cox. He states that about twelve months ago he first perceived a hard wart growing out from the left side of the scrotum, to the extent of two inches in length; he cut it off near to the scrotum with a razor; the raw surface ulcerated, and from the ulceration, according to his account, small lumps appeared, one after the other, "like a bunch of grapes." The ulceration gradually increased, until it attained the size of the bottom of a wine-glass, and then, (about three months ago,) it began to discharge a thick, green, and very offensive matter; it has not spread much

lately, but the pain has been most intense within this last month; it itches much, and when he scratches it, it bursts out bleeding slightly; he describes the blood as being pale. His health has always been very good. His parents appear to have died consumptive. He ascribes the disease to the irritation caused by the lodgement of soot in the scrotum. He is not subject to cough. Has tried caustics, but without any relief.

Present state:—There is a large ulcer, in size rather larger than the bottom of a wine-glass, with elevated, indurated, and irregular edges, situated on the left side of the scrotum, and occupying nearly the whole of the left side of this part, and extending to the junction of the left thigh with the scrotum; it appears to be spreading towards the right side, where are some indurated lumps, resembling those which appeared first on the left side. There is no appearance of granulations in the wound; the inguinal glands are indurated, and are also enlarged, and pain him much at times; he, however, states that the glands were enlarged previous to the appearance of the disease. He complains of much pain in the wound, described as lancinating, extending from the wound to the glands in the groin, and along the penis, and also down the thigh nearly as far as the knee; the pain is not constant, but is always worse at night; the pain sometimes shoots up as high as the ribs on the left side. The left testicle is not any harder than the right, which appears healthy, but it seems to be adherent to the scrotum, opposite to the ulceration; the spermatic cord does not appear to be affected. Pulse 86, full and regular; bowels open; tongue clean; appetite good; he sleeps indifferently at night, the pain preventing him from doing so; the discharge from the wound is thin, and of a yellow colour, very offensive, and tinges the cloths (he states,) of a blackish colour.

November 5th. The disease has slightly spread since last report, it occupies half of the scrotum, and is extending towards the lower part; the pain is much complained of at night; has been poulticing it lately, but it does not discharge much.

20th. Has been into the country for a short time, he returned this morning; the disease has made progress, having extended more towards the left thigh, and towards the lower part of the scrotum of the opposite side; the pain is rather worse, but his health is good; wishes much to have the disease removed. Pulv. Opii, gr. iss.; Conf. q.s. ut fiat pil. omni nocte.

21st. The operation for the excision of the diseased mass was performed by Mr. Cox in the following manner:—An incision was made on each side of the diseased mass, which was then dissected off from the parts beneath, so that both testicles were fully exposed; the left testicle was found adherent by its outer tunics to the diseased mass; these adhesions were next cut through, and the diseased scrotum removed. The left testicle was attentively examined; the outer tunics were found indurated, and apparently diseased, so that its removal was decided upon; pressure was made on the external abdominal ring, and the cord being exposed and isolated, a ligature was slightly tied around it and its vessels, and it was divided by placing the knife

underneath it, and cutting outwards; the cellular connections were separated with a few touches of the knife, and the testicle removed; three of the vessels of the cord required ligatures; another small vessel on the inner part of the thigh also required to be ligatured. There was but little of the scrotum left for the covering of the testicle, the edges of it were united by six stitches; strips of adhesive plaster were applied over these, and the whole supported by a T bandage. He bore this painful operation with great fortitude.

The diseased mass measured four inches by three inches, and weighed four ounces; the elevated indurated edges offered more resistance to the knife than the parts which they enclosed; the cut surface had a striated appearance, but did not glisten or exhibit the fibrous bands of scirrhus. A small portion examined under the microscope presented nucleated cells, and a number of granules, of a yellowish colour.

4 p.m. Has been sick, probably from the wine which he imbibed during the operation; complains of but little pain; pulse 120, soft; tongue clean. Mist. Salin., oz. iss., quartis horis. Broth diet.

22nd. Slept well last night; no sickness; complains of some slight pain in the wound; pulse 120, soft; tongue slightly coated; is rather thirsty; skin moist. Continue the medicines.

23rd. Feels pretty comfortable; some slight pain in the head; bowels not open; tongue slightly coated; pulse 118, soft; appetite good; the wound looks healthy, but discharges a foetid pus. Extra meat diet. Extr. Col. Co., (Palmeri), gr. x., hora somni sumendus.

24th. Wound looks healthy; there is some slight enlargement of the right testicle, which is well covered by the remaining part of the scrotum; pulse 110; tongue clean; slight pain in the epigastric region; slept pretty well last night; bowels open.

26th. Feels comfortable; tongue clean; appetite good; pulse 96, soft; sleeps well; complains of slight shooting pain in the wound; wound looks healthy. To be dressed with water dressing.

28th. Doing well; no increase in the swelling of the remaining testicle; sleeps well; there is some œdema of the prepuce; appetite good; tongue clean; pulse 97; bowels confined. Rep. Extr. Colocynth. Comp., gr. x., hora somni.

December 1st. Improving; bowels open; pulse 92; perspired a good deal last night; there is increased œdema of the prepuce; the wound is uniting, looks healthy, and discharges slightly.

3rd. An abscess has formed on the penis, just below the prepuce; it was opened, and some healthy matter let out; the edges of the wound on the scrotum have united at intervals, the intervening parts filling up by granulation; the wound looks healthy; pulse 90, soft; sleeps well; appetite good; bowels open.

9th. The swelling of the penis has quite subsided, and the abscess is healed; the wound is rapidly healing; does not complain of pain; general health good.

15th. Doing well; the wound is nearly healed over; no pain; health much improved.

19th. For the last three days he has complained of

jumping, afterwards aching, pain, in the right side of the scrotum; it much resembles the pain which accompanied the previous disease; pulse 108, small; feels low; the scrotum and penis appear inflamed, and feel hot. Ordered to keep the parts constantly damp with cold water.

23rd. Pain quite gone; inflammation subsided; the wound is nearly healed; health good.

27th. Better in every respect; is sitting up.

January 4th, 1847. Wound quite healed; general health good. Discharged cured.

May 20th. Presented himself at the Hospital; his health is much improved, and there is no symptom of any return of the disease.

September 6th. Was seen to-day in good health; there is not the slightest appearance of any return of the disease.

Chimney-sweepers are liable to two distinct affections of the scrotum, which, although they differ very greatly in their nature, and in their consequences, are yet constantly described as the same affection, under the name of chimney-sweepers' cancer.

Both of these affections are produced by the irritation which is caused by the accumulation of particles of soot in the moist rugæ of the scrotum, and it is not difficult to conceive why the disease should generally begin in that part; but true soot-wart has been seen in the face of a chimney-sweeper, just under the left eye, who had never suffered from the disease in any other part, though he said he had sometimes felt little hardiness in the scrotum, which, when they grew troublesome, he picked them off, but he had never perceived any sore, ulceration, or considerable hardness in that part. A case is recorded of this variety of cancer occurring in the right hand of a gardener, who for years had been in the habit of sprinkling soot over his flower-beds with his hands.

The most common of these affections of the scrotum consists in the development of tubercles, which subsequently become affected with uncontrollable ulceration.

The other affection, which is much less common than that just described, consists in the deposit of true carcinomatous matter in the texture of the scrotum, which subsequently ulcerates, and passes through its usual course. The fact of these two affections being constantly confounded, fully accounts for the discordant descriptions given by different authors of the course and consequences of the disease. Some authors affirm that the lymphatic glands scarcely ever become affected, while others on the contrary describe the inguinal and lumbar glands as being almost constantly contaminated. Again, with reference to the results of operation. Mr. Travers and others are of opinion that the disease will almost always return, even after the most extensive removal, while others consider the operation as being almost always successful.

If the disease be of the first-mentioned description, the lymphatic glands in the groin may become enlarged from irritation only, and the disease itself, if removed, will not reappear; but in the second class of cases, the lymphatic and lumbar glands become affected with

carcinomatous deposit, and the disease, if removed, will be almost certain to return.

The malignant form of the disease termed cancer scroti, is frequently hereditary. Mr. Earle has operated on a man whose grandfather, father, and brother, had fallen victims to this disease; and other cases of the same kind are recorded. It is said to be most common between the ages of 20 and 40. The ages at the time of death of nine persons, as recorded in the reports of the Registrar-General, are—28, 30, 32, 38, 45, 48, 50, 54, 60. Sir James Earle mentions a case in a lad under eight years of age; and Mr. Samuel Cooper has seen a case in a boy not more than sixteen.

The average duration of this disease has not yet been ascertained with accuracy; it varies, however, from some months to several years, and its fatal termination is sometimes hastened by hæmorrhage, owing to the destruction of the coats of an artery.

Removal of the diseased parts by the knife is the only efficacious method of treating both the affections which are described as cancer of the scrotum, and should be at once resorted to in all cases of the non-malignant variety, and also in all those cases of true cancer scroti in which the disease has not made much progress, and where the spermatic cord and inguinal glands are not obviously affected.

In the above case so much of the scrotum was removed, that even the remaining testicle had scarcely sufficient covering. This, Mr. Liston states, is of little consequence, for the glands soon receive a covering at the expense of the surrounding healthy skin, together with the cicatrix formed by the granulations; in fact, Mr. Liston says, the removal of the whole scrotum would be supplied by a very effectual substitute. This is perhaps accounted for by the fact that the testicles are supplied with blood from a part of the body very distant from that which supplies the scrotum.

The removal of the left testicle was quite necessary in the above case; it had a very suspicious appearance, and the small speck noticed upon it, at the spot where it was adherent to the scrotum, was probably an extension of the disease.

PROVINCIAL

Medical & Surgical Journal.

WEDNESDAY, MARCH 7, 1849.

Owing to the importance of the late meeting of the Poor-Law Medical Officers, and our desire to give as full an account as possible of the proceedings at and connected with the meeting, we are compelled to limit any observations which we might otherwise have had to make on the subject, to a very brief recommendation of it to the serious consideration of all who are interested in its settlement. At the same time we would request the attention of the Members of the

Provincial Medical and Surgical Association, (many of whom are Poor-Law Medical Officers, and all of whom we believe to be deeply impressed with a sympathizing feeling for the degradation, insults, and oppression, to which so numerous and meritorious a portion of our medical brethren are continually subjected,) to the letter of Mr. Martin of Reigate, on the bearings on this question, of a reform, or rather reconstitution, of all our medical institutions. Mr. Martin is, we feel assured, correct in the position which he has taken up, and it is with reluctance that we content ourselves with this brief reference to his letter and the resolution proposed by Mr. Wyld. Both, however, speak sufficiently for themselves, and for the rest our readers are but too well acquainted with the imperative necessity which exists for a speedy alteration of the present most unsatisfactory and worse than unsatisfactory position in which the entire medical profession is placed.

Reviews.

Surgical Anatomy. By JOSEPH MACLISE, Surgeon. FASCICULUS I. London: Churchill. Folio. Plates.

We are informed in the preface that "the object of this work is to present to the student of medicine and the practitioner removed from the schools, a series of dissections demonstrative of the relative anatomy of the principal regions of the human body." Such is, indeed, the main utility of all representations of this class, for, as the author subsequently observes,—"An anatomical illustration enters the understanding straightforward in a direct passage, and is almost independent of written language. A picture of form is a proposition which solves itself," and "the best substitution for nature itself, upon which to teach the knowledge of her, is an exact representation of her form." Hence a work like the present, which represents with truth and fidelity the forms which nature reveals, is equally calculated to indicate to the inexperienced student what he is especially to look for, and to recal to the recollection of the practitioner, and to assist in impressing on his mind, those lessons which he had before imbibed, but which the lapse of time, and the multitude of objects of various descriptions ever pressing on his attention, tend much to weaken or efface.

"Every surgical anatomist," says the author, "will (if he examine himself,) perceive that previously to undertaking the performance of an operation upon

the living body, he stands reassured and self-reliant in that degree in which he is capable of conjuring up before his mental vision a distinct picture of his subject."—"The unbroken surface of the human figure is as a map to the surgeon, explanatory of the anatomy arranged beneath;"—"We dissect the dead animal body in order to furnish the memory with as clear an account of the structure contained in its living representative, which we are not allowed to analyse, as if this latter were perfectly translucent, and directly demonstrative of its component parts.

These observations speak for themselves, and need no comment. It is sufficient to say that the manner in which the author has carried out his design is such as completely to fulfil the intention. The fasciculus before us consists of four plates, each containing two figures, with a commentary and description attached. The subjects of the four first plates are—1. The form of the thoracic cavity, and the position of the lungs, heart, and larger blood-vessels. 2. The surgical form of the superficial, cervical, and facial regions, and the relative position of the principal blood-vessels, nerves, &c. 3. The surgical form of the deep cervical and facial regions, and the relative position of the principal blood-vessels, nerves, &c. 4. The surgical dissection of the subclavian and carotid regions, and the relative anatomy of their contents.

It will thus be perceived that the physician is almost as much interested in this work as the surgeon, and we have only to add in conclusion, that while in the fidelity and correctness of the representations, and in the beauty of the delineations, it is surpassed by no work which we have seen, its price is so low as to bring it within the reach of all. Nothing but a large circulation can secure either to author or publisher that remuneration which its great excellence, and the manner in which it is got up, so justly deserve. The best we can desire for both parties, as well as for the benefit of the profession, is that the circulation may be equal to the merits of the work.

Proceedings of Societies.

SHEFFIELD MEDICAL SOCIETY.

Fifth Meeting, Nov. 30, 1848.

The President, Dr. BARTOLOME, in the Chair.

SCIRRHOUS PYLORUS, WITH ABSCESS OF THE LIVER.

Mr. Porter exhibited the stomach and a portion of the liver of a man, aged 58. Until the last year or two his habits were intemperate; he became a dispensary patient four months ago. There was much emaciation, and he complained of pain at the pit of the stomach, which was not much aggravated by taking food. He had no vomiting until two days before his death, and then, according to his wife's account, he ejected "what was like matter from an old abscess." No distinct tumour could be felt in the epigastrium. The liver was

hard and easily felt. The case was considered to be scirrhus of the liver. On *post-mortem* inspection the stomach and liver were found to be united by a very firm adhesion, and in their removal the finger passed into an abscess of the left lobe, and penetrated the mass of scirrhus at the pyloric extremity of the stomach, which adhered to the under surface of the left lobe.

OVARIOTOMY.

Dr. Branson gave an account of a case of ovarian disease, for which the operation of ovariectomy was performed by Dr. Clay, of Manchester. Dr. Clay was present at the meeting, and at the conclusion of the paper gave a full account of the results of ovariectomy in his own practice.

The patient was a young lady, just turned eighteen, at the time of the operation, and the disease had then existed three years. She first remarked a small tumour in the right groin, in the spring of 1845; this slowly increased in size, and at length occasioned considerable alarm to her friends. The tumour was pronounced to be ovarian, and was tapped January 5, 1847. This was followed by great relief; it enabled her, comparatively speaking, to enjoy life, and even to take a moderate amount of exercise. Her general appearance at this time was tolerably healthy, and there was no loss of flesh. A portion of the tumour was evidently solid, and could be felt after the tapping, in the opposite side to which it had been felt in previously, thus proving the mobility of the tumour. This comfortable state gradually gave place to a repetition of the previous symptoms, and in the spring of 1848 the tumour had again become so distressingly large, as to necessitate another tapping on the 24th of April. The relief now experienced was very transient; the tumour filled again rapidly, and on June 5th, six weeks only after the previous tapping, the operation was again performed. Her strength now began to fail; she could not walk more than a hundred yards without fatigue, and was obliged to be wheeled about in a garden chair. The complexion continued so healthy, as to preclude the suspicion of malignant disease; and as she had never suffered from much pain in the tumour, beyond the inconvenience arising from its bulk, there was no reason for supposing that any peritoneal inflammation had at any time existed. Still she grew thinner, and her finger rings became too large for her, a positive proof that the process of absorption was now going on rapidly. About ten days after the last tapping, on June 5th, the wound made by the trocar spontaneously re-opened, and a considerable discharge of fluid took place, and continued, more or less, for some days. The discharged fluid was most probably ascitic, for the general size of the tumour was not very materially diminished by its evacuation. The catamenia had never appeared. The advice of Dr. Clay was now sought, and Dr. Branson met him in consultation. The abdomen seemed as much distended as in the last period of pregnancy. A solid tumour, of a somewhat oblong form, supposed, by Dr. Clay, to weigh five or six pounds, was distinctly felt rising upwards, from the situation of the right ovary; two other sacs were supposed to exist, one of moderate size which occupied the umbilical region, and one much larger which occupied nearly the whole of the left side of the abdomen. It was thought that the

smaller sac only had been pierced at the last tapping. The whole tumour was certainly moveable, and as traction of the tumour from various points produced no sense of dragging or pain, Dr. Clay was satisfied there existed no formidable adhesions. A careful uterine examination was also made, and the uterus was pronounced free from disease, nor could any trace of disease be detected in any other vital organ. All these circumstances having been taken into consideration, Dr. Clay gave a decided opinion that the case was a fair one for operation, at the same time it is only justice to him to say, that there was no concealment whatever on his part, from the friends of the patient, of the great danger attendant upon the operation, nor was the dark side of the picture ever tempered with a specious colouring. At length, after anxious consideration, it was determined to state the case candidly to the young lady herself, leaving the decision of the question to her alone, and the issue in God's hands. She resolved, with calm determination, to submit to the operation, and steadily looked forward to the hazardous prospect of relief with unwavering firmness.

The bowels having been carefully regulated for some days previously, and the general health being in as satisfactory a state as could, under the circumstances, be expected, Dr. Clay commenced the operation in a room properly heated for the purpose, the patient being under the influence of chloroform. It was previously agreed upon that a small exploratory incision should first be made, and in the event of any formidable adhesions being met with, the wound was to be immediately closed, and the operation abandoned. This was carefully done; a considerable quantity of ascitic fluid escaped, and as no adhesions whatever could be felt on the anterior surface of the tumour, the wound was rapidly enlarged upwards and downwards, to the extent of about nine or ten inches. This brought the tumour fairly into view, bulging out from the lips of the wound. To lessen the bulk of the tumour, the largest cyst was punctured, and about five or six pints of gummy glairy fluid drawn off, very different in character from that which escaped spontaneously after the last tapping. On attempting to raise the mass (for the solid portion of the tumour was larger than had previously been imagined,) it was found to be tied down posteriorly to the omentum by several bands of lymph, and at one point it was adherent to the bowel. These adhesions were easily peeled off; the pedicle was grasped and tied with a double ligature, and the tumour separated and removed. The wound was then rapidly closed, and held together by six or seven interrupted sutures, the whole operation occupying fifteen minutes, and in little more than twenty minutes' time from the commencement of the operation, the bandages were applied, and the patient again in bed. The action of chloroform was apparently most satisfactory; she lay as in a calm sleep, perfectly unconscious, till nearly the last suture was introduced, when she awoke, and expressed great thankfulness that the operation had been so painlessly performed. For the first twenty-four hours all went on well; she was cheerful and comfortable, and complained of no pain nor uneasiness whatever; there was no thirst nor sickness, and the pulse, which had never been less than 100 for some time before the operation,

was scarcely accelerated; the urine was passed naturally, and she enjoyed several hours comfortable sleep. The rest is soon told. At the end of twenty-four hours the pulse was quicker, though not of a character to indicate inflammatory action, or to justify depletion. The bowels had not acted, still there was no abdominal tenderness, the skin was soft and moist, and the countenance remained free from any indication of distress. She spoke, and smiled cheerfully; even thirty hours after the operation she was thought to be progressing favourably; the system, however, was now becoming alarmed; the breathing was somewhat quickened, the pulse had become rather more frequent, and she had vomited two or three times. There was still no action of the bowels. At four o'clock in the morning, thirty-eight hours after the operation, she became suddenly worse; she complained much of flatulency, the countenance was anxious, the respiration hurried, and to these unfavourable symptoms was added general restlessness; this was followed by rapid sinking, and she died forty-four hours after the operation, apparently from the shock of the operation, and not from peritoneal inflammation.

The solid portion of the tumour was found to exceed considerably all previous calculation; it passed backwards towards the spine, thus rendering external manipulation of little avail in calculating its bulk. It weighed twelve pounds; and as about six pounds of cystic fluid, and at least nine or ten of ascitic fluid, were also drawn off, the abnormal contents of the abdomen must have amounted to nearly thirty pounds. The tumour did not consist, as was supposed, of a solid mass, and two separate cysts, but was made up of innumerable cysts, varying much in size, from that of a pea, to one containing several pounds. The solid portion was also composed of cysts, containing a semi-fluid, dark-coloured, grumous, and brain-like matter; it is evident, therefore, how small an amount of relief would be gained by tapping.

Dr. Branson first noticed the propriety of the operation about which so much difference of opinion exists. The question seems to turn upon the probable duration of uncontrolled ovarian disease. There are legitimate operations in surgery as fatal as ovariectomy, but they are nearly all performed in the hope of averting certain and immediate death, whereas the operation of ovariectomy must ever encounter the risk, even in the best selected cases, of shortening a life which might have been prolonged to an indefinite period. Those who have paid the greatest attention to the statistics of ovarian disease, place the average duration of the complaint at little more than three years. Exceptional cases are met with, in which the constitutional symptoms are trifling, the patient suffering only from the bulk of the tumour. These cases so obviously unsuitable for ovariectomy, may be excluded from the question. Is, then, an average duration of three years sufficient to justify the operation? Have we, under any circumstances, a right to hazard an operation which may probably thus much curtail life? A combination of the following circumstances seems to answer the question in the affirmative,—viz., when the tumour is large, partially solid, or composed of numerous cysts, the walls of which require a large amount of blood for their nutriment;—when tapping ceases to afford relief

and the growth of the tumour is rapidly going on at the expense of the general system as evidenced by the loss of flesh;—when the uterus is perfectly free from disease and there is no evidence of mischief in any other vital organ;—when the tumour is clearly moveable, and no evidence of previous peritoneal inflammation exists;—when no relief can be obtained by any other means;—when medicines are powerless, and subcutaneous sections and small incisions useless;—when the patient herself, after a full and candid explanation of its dangers, prefers to submit to the hazard of an operation with the chance of a perfect cure, rather than linger out a painful existence for a few short months—then, and then only, ought the operation to be performed. The difficulty of diagnosis in some cases and the impossibility of deciding with certainty upon the presence or absence of adhesions must ever prove the greatest obstacles to the reception of this operation by the profession. With regard to adhesions the case just related proves too plainly that no amount of skill or experience can decide the question even with the aid of an exploratory incision. The tumour may be perfectly moveable, it may roll easily under the fingers, and yet be bound down posteriorly by firm adhesions. The mobility of the tumour, the best test we have, only proves the non-existence of adhesions between the tumour and the abdominal walls; a posterior adhesion, it is evident, will admit of lateral motion, and form a hinge on which the tumour may turn. The presence of ascitic fluid may be considered rather favourable than otherwise, since it tends to prevent that close contact between the tumour and the abdominal walls so necessary for the formation of adhesions. As the size of the tumour in this case rendered a large incision absolutely necessary, Dr. Branson did not discuss at any length whether a large or small section is to be preferred. The danger does not appear to be materially increased by the length of the incision, and the facility which the large incision affords to the operator of grasping and tying the pedicle is a strong argument in its favour. Besides, it is questionable, whether cases which admit of operation by the small incision are suitable for the operation at all. Ovariectomy should ever be considered as the last resource of our art, and be restricted to solid rapidly-increasing tumours, or tumours composed of numerous cysts, at a time when tapping is powerless for relief, and early death certain. It is true, that a simple unadherent cyst may be punctured and withdrawn through a small abdominal opening; yet, here there can be no certainty that the case might not have proved one of those exceptional cases in which life is prolonged for a considerable period without the hazard of a peritoneal section. Dr. Branson, in conclusion, expressed his best thanks to Dr. Clay, for courteously allowing the use of a case, which more properly belonged to him, and instanced it as an additional proof to those already existing in his useful journal, that concealment of the results of ovariectomy formed no part of Dr. Clay's policy.

Dr. Clay then gave an account of the results of ovariectomy in his own practice. He said the operation had been brought under his notice by Mr. Lizars in 1822, and in 1842 he performed his first operation. His three first operations were successful. He had now

opened the abdominal cavity 39 times. Dr. Clay gave the following analysis of the results of his operations:—

- 1—Purely uterine; fatal immediately after the operation; diagnosed correctly as fleshy tubercle of the uterus; the tumour weighed twenty-seven or twenty-eight pounds.
- 1—Large uterine tumour with ovarian disease. Fatal.
- 1—Large ovarian tumour with enlargement of the uterus. Tumour and uterus removed. Fatal from the effect of a fall on the fourteenth day after the operation. The incision had healed, and the patient was apparently convalescent.
- 5—Exploratory only; the operation not proceeded with; of these, four recovered, and one died twenty days after the operation.
- 31—Cases of uncomplicated ovarian disease. Of these, 22 recovered and 9 died. One has since died of fever, five years after the operation.

Recoveries (including exploratory incisions) 26.
Deaths 13.

Dr. Clay was rather doubtful as to the value of chloroform in ovariectomy. The two cases in which he had used it were both fatal. In other operations he had used it with the best results. He had less dread of adhesions now than formerly, and he would now have completed the operation in three out of the five exploratory cases in which the operation was abandoned. On meeting with a very firm adhesion, he would in future adopt the plan of cutting round the adhesion, leaving the adherent portion of the sac attached to the abdominal parietes, omentum, or bowel. The majority of cases of ovarian disease are situated in the right ovary. He had examined nearly five hundred cases, and four fifths were of the right ovary. He considered that tapping should be deferred as long as possible; when once performed it must be repeated more and more frequently till it becomes necessary every ten or fifteen days. Dr. Bird's plan of a small incision is not applicable in large and solid ovarian tumours, or where any adhesions exist; nor could Mr. Brown's plan of compression succeed in large and solid tumours. Three of Dr. Clay's cases were successful from the ulcerative process, the removal of the disease being impracticable. He considered the temperature of the room at the time of the operation of the greatest importance; the operation should never be commenced if the temperature of the room is below 71 or 72 degrees, and on this account he preferred a small room to a large one for the operation, as being more readily heated. One of Dr. Clay's patients became pregnant after the removal of one ovary, thus proving the sufficiency of one ovary for the process of conception. He regarded the third and ninth days after the operation as peculiarly critical.

CONVENTION OF POOR-LAW MEDICAL OFFICERS.

The general meeting of Poor-Law Medical Officers took place, according to previous notice, on Monday, February 19th, at the Hanover Square Rooms, the Right Hon. the Lord Ashley in the Chair.

The Noble Chairman, on opening the proceedings, remarked—No one could read the copious evidence taken in 1844 by the Committee of the House of Commons, of which he was Chairman, on the subject of medical relief for the sick poor, without coming to the conclusion that the relief afforded to them was insufficient, and the remuneration which was granted for medical services inconsistent with the honourable position which professional gentlemen occupied. He had always been of the opinion which he had stated on that Committee, that the medical officers appointed under the Poor-Laws could not properly discharge their onerous duties unless they received an income suitable to the laborious offices they had to perform, and were rendered independent of the caprices of the Boards of Guardians. They should be enabled to occupy the position of persons who, knowing that they had grave and arduous functions to discharge, should be responsible to professional authority and supervision, instead of being subject to the capricious control of men often ignorant, and sometimes insolent. He thought, also, that their situations ought to be permanent, for their duties were of the most complex and burdensome kind, and the cases which they encountered in their practice demanded a greater degree of responsibility and labour than fell on those who were engaged in administering medical aid to the higher classes; for it was a recognized fact, that not only were the most complicated cases in medicine and surgery found among the working people, but their treatment was rendered more difficult, in consequence of the previous habits and mode of life of the patients. When, therefore, they found gentlemen of education and character entrusted with the charge of perhaps ten or twenty thousand persons, and paid by a miserable pittance scarcely sufficient to provide the necessary medicines, their position became an insult at once to the poor and to the profession to which they belonged. He trusted, therefore, that they would henceforward persevere in maintaining the organization they had formed for the assertion of their claims, and continue to press on the Legislature the propriety of introducing a system which would enable them to render to the poor the amount of relief demanded not merely by justice, but by the first instincts of humanity. He would be most happy to render them all the assistance in his power to advance their cause. He would not promise to undertake any legislative interference for them; but if he could be of service to them in any other way than by the introduction of a legislative proposition, which the present amount of his parliamentary duties forbade him to undertake, they should find him ready to support them, because he felt that he would be serving not merely the numerous class of medical men discharging duties under the Poor Law Act, but the far more numerous class of the suffering, sick, and destitute poor.

Mr. C. F. J. Lord read a report from the committee appointed at a former meeting, from which it appeared that they had received from district surgeons 805 reports as to the working of poor-law medical relief. It was also stated that the most encouraging assurances of good fellow-feeling had been received by their deputations to the Colleges of Surgeons and Physicians and the Society of Apothecaries. The account of the interview between

members of their profession and the Secretary of State for the Home Department and the President of the Poor-Law Commissioners, was adverted to, and the profession was reminded that the President of the Poor-Law Board had stated, that he was inclined to consider medical relief as *a question distinct from ordinary poor-law administration, and one which should be put on a separate and more comprehensive footing.* At the meeting of the Provincial Medical and Surgical Association, which was held last autumn, at Bath, they had also received encouragement and promises of co-operation. The report stated that out of the £8,000,000 raised for the nominal relief of 3,000,000 of poor, the largest amount divided in any one year among the 3000 gentlemen engaged in administering medical relief to them was £175,000, in return for journeys through the country, medicines, professional skill, &c. ! The cost of drugs required in each case of illness attended in hospitals was 4s. 2d.; in dispensaries, 2s. 5d.; while in urban unions only 1s. 6d. was allowed, and in rural unions, 2s. 2½d. The opinion of Sir George Grey was quoted, "that the question of expense was subordinate to what was necessary to secure efficient medical relief." A statement of receipts and expenditure of the committee was appended to the report, from which it appeared that the subscriptions received had been insufficient to cover the outlay, and that a sum of £22 17s. 9d. was due to the treasurer.

The report was then received and adopted.

Moved by Wm. Lobb, Esq., seconded by Peter Martin, Esq., of Reigate, and resolved unanimously :—

"That the evidence laid before this Convention and the correspondence of its Committee, prove an universal and increasing dissatisfaction among the medical officers of unions,—that how much soever the Poor-Law Board may feel the necessity of altering the present vicious system of poor-law medical relief, they are so hampered by the Boards of Guardians, that they are unable to carry into operation the very measures which they have deemed to be right; there is, therefore, great cause for the medical profession, and the poor-law medical staff more especially, to seek directly, from Parliament, redress from the hardships and injustice under which the sick-poor and the union surgeons are suffering while the present system continues, it is therefore urged, that as the Government at present pay half the medical salaries, it is expedient that it should pay the whole, and remove from Boards of Guardians the power to interfere with wise regulations and salutary improvements."

Mr. Martin observed that there was a strong feeling among the profession in favour of placing the whole charge for medical relief on the consolidated fund, and thus depriving the guardians of any ground for the idea that all the money paid to surgeons came out of their own pockets. The present time was favourable for attempting the change, and if that first step were taken, other ameliorations would very soon follow. The resolution then passed unanimously.

Moved by John Liddle, Esq., seconded by James Lord, Esq., and resolved,—“That the plan for an improved system of medical relief, suggested by the Committee of the Convention, and laid before the government in their memorial to the Right Hon. Sir George Grey, contains the three important principles which are best calculated to render any system acceptable to the medical profession, and in the highest degree useful to the poor,—viz., *payment proportioned to duties, permanence of appointment, and responsibility to professional authority.*”

Mr. Liddle believed it was admitted universally, that so long as medical officers were subject to the control

of Boards of Guardians, there was no hope of improvement in their condition. They knew nothing of the labour, expense, and sacrifices by which professional competency was attained, and they thought that men were sufficiently paid by the honour of being elected to the office! A great number of surgeons were elected annually, and if they ran counter to the guardians, by recommending more relief from the workhouse than they liked, they very soon said to them, "We know what to do with you next year." In support of the opinion that the most proper authority to which they could be subjected was professional authority, he quoted Dr. Southwood Smith, who recommended that the inspection and supervision which worked so well in military hospitals, should be extended to union surgeons, and expressly stated that the Boards of Guardians were altogether incompetent—nay, that there were occasions when the Poor-Law Commissioners themselves would be in need of the advice and assistance of a qualified superintending medical officer.

Moved by Dr. Sibson, seconded by Edward Bainbridge, Esq., of Tooting, and resolved,—“That the Board of Health having imposed upon the Poor-Law Medical Staff, through powers given in the ‘Nuisance Removal and Diseases Prevention Act,’ new duties of a distinct kind, relating to sanitary purposes, without providing payment for the same, this meeting claims protection against such exaction.”

Mr. Wyld, M.P., here addressed the meeting on the topics embraced by the resolutions, and proposed a motion for the total reform of the profession, but which, not having been submitted to the Committee previous to the meeting, was not put from the chair.

Moved by Edward Daniell, Esq., of Newport Pagnell, seconded by Henry W. Livett, Esq., of Wells, Somerset, and resolved,—“That a petition be presented to Parliament, praying the Legislature to pass an Act embodying the principles alluded to in the previous resolutions, and that the members of the medical profession, the poor-law medical staff more especially, and all others interested in behalf of the sick-poor, in improving the present system of poor-law medical relief, be requested to use their utmost personal influence with members of Parliament for the attainment of this object.”

Moved by William Cantrell, Esq., of Wirksworth, seconded by J. S. Soden, Esq., late of Bath,—“That a Committee shall still be maintained, for which purpose the following gentlemen be re-appointed, with power to add to their number:—

Thomas Hodgkin, M.D., *Chairman*, Lower Brook Street, Grosvenor Square.

Thomas Martin, Esq., *Treasurer*, Reigate.

Charles F. J. Lord, Esq., *Honorary Secretary*, Hampstead.

Adolphus Barnett, Esq., Limehouse; John Liddle, Esq., Alie Place, Goodman's Fields; William Lobb, Esq., Aldersgate Street; George Ross, Esq., Farrington Street; Josh. Thomas Mitchell, Esq., Kennington; James F. Vallance, Esq., Stratford; Edward White, Esq., Lamb's Conduit Street; James Heygate, Esq., M.D., Derby; Peter Martin, Esq., Reigate; Edwd. Boulger, Esq., Blechingley; Geo. Bottomley, Esq., Croydon; Wm. Cantrell, Esq., Wirksworth, Derby; Edward Daniell, Esq., Newport Pagnell; Alfred Ebsworth, Esq., Bulwell, Notts; John Burton, M.D., Walsall, Stafford; Thos. Parker, Esq., Woburn, Beds; Rich. Thos. Tasker, Esq., Melbourne, Derby; Henry W. Livett, Esq., Wells, Somerset; John A. Pearson, Esq., Woolton, Liverpool; James Stedman, Esq., Guildford; Thos. H. Smith, Esq., St. Mary's Cray; and that it is essentially necessary that a more liberal

contribution be solicited from the Poor-Law Medical Staff, and the profession generally, to sustain the objects of the Convention, otherwise it will be impossible for the Committee to continue their exertions.”

Moved by C. M. Thompson, Esq., of Westerham, seconded by James Stedman, Esq., Guildford, and resolved,—“That this Convention publicly records its sense of obligation to the Colleges of Physicians and Surgeons, the Society of Apothecaries, and very prominently to the National Institute of Medicine, Surgery, and Midwifery, and the Provincial Medical and Surgical Association, as also to the medical and general press, for the support which all have rendered to the Poor-Law Medical Officers and the sick-poor, a continuation of which co-operation and advocacy is earnestly requested, until the objects of the Convention shall be happily realized.”

Moved by James Vallance, Esq., of Stratford, seconded by Dr. Barnett, and resolved,—“That the thanks of this meeting are eminently due, and are hereby given, to its eminent Chairman, Lord Ashley, for his unceasing efforts to benefit the sick poor. And having full confidence in his Lordship as to his desire to see justice done to medical officers of Unions, this meeting earnestly requests his Lordship to kindly undertake the advocacy of the cause of the sick poor and of the Poor-Law Medical Officers, in Parliament or otherwise, in such manner as to his Lordship may seem most advisable, in order to obtain a final adjustment of the long agitated question of the Poor-Law Medical Relief.”

Moved by William Lobb, Esq., seconded by C. F. Lord, Esq., and resolved,—“That the thanks of this meeting are eminently due, and are hereby given, to Dr. Hodgkin, for his urbane and able conduct in the chair of the Committee, and for his long advocacy of the cause of the Poor-Law Medical Staff.”

It is with regret that we have been unable to find room for the eloquent speech of Mr. Daniell of Newport Pagnell, and to report the proceedings generally at greater length; but being desirous of giving insertion to the subjoined digest of some of the communications made to the Committee, drawn up by Mr. Lord, the Honorary Secretary, we have thought it more advisable on the present occasion to confine our account of the meeting to the notice which has appeared in the columns of the *Lancet*.

ABSTRACT OF COMMUNICATIONS MADE TO THE COMMITTEE.

Mr. Armitage Pearson, of Woolton, one of the first opposers to the exactions made upon medical officers by the recent sanitary regulations, issued by the Board of Health, forwarded from the West Derby Union a *protest*, signed by thirteen medical officers, against the imposition of such duties, and another of a similar character from the Prescott Union with five signatures attached.

In the first of these documents, the disclaimers pronounce the regulations in question to be “*such as sacrifice their rights, not only as medical officers but as private citizens*,” the second declares such exaction of services to be a “*violation of their contracts and an infringement of the just rights of all Union surgeons*.”

Mr. W. H. Smith, of St. Mary's Cray, unable to be present from indisposition, drew the attention of the Committee, by letter, to an assurance made by Lord Lansdowne, in his place in the House, that “*the Government were pledged by him, that sanitary duties should not be required without being paid for*.” Mr. Smith adds, that “*Lord Wynford is ready at any time*

to question Lord Lansdowne on the matter in the House, should a necessity arise."

The following copy of a resolution, passed at a meeting of the medical officers of the Bakewell Union, held on the 13th instant, was presented by Mr. Cantrell, of Worksworth, a gentleman who, from the commencement of the present agitation, has been most zealous in furthering the objects of the Convention:—

"That the full concurrence of this meeting be given to the objects and intentions of the Poor-Law Medical Convention, and that Wm. Cantrell, Esq., be deputed to attend the meeting of the Poor-Law Medical Officers, to be held in London on the 19th instant." Similar resolutions were also presented by Mr. Cantrell from the Belper and Ashbourne Unions.

A letter was received from Mr. Wakley, M.P., intimating his intention to attend the meeting, who, however, from some unassigned cause [We regret to state, from illness] was unable to be present.

The President of the Provincial Medical and Surgical Association, Mr. Norman, of Bath, being unable to be present at the general meeting, and feeling kindly alive to the objects of the Convention, obtained a substitute in the person of Mr. Soden, formerly of that city, who obligingly attended, and represented him on the occasion by seconding the fourth resolution.

Dr. Cowan, of Reading, a member of the Council of the Provincial Association, and a warm advocate of the cause of the Union Surgeons, wrote expressing his regret at being prevented from attending and raising his voice in furtherance of the objects of the meeting.

Mr. Torrance, of Rugby, attended on behalf of five colleagues,—medical officers of the Rugby Union, and, in tendering a contribution from each, assured the Committee of the sympathy and thankfulness with which they noticed their exertions in furthering the interests of the Union Surgeons.

A letter was received from Mr. Hardwick, of Hempsall, Norfolk, expressing hearty interest in the proceedings of the Convention, enclosing a contribution, and subscribing himself "A much injured surgeon, and sincere well-wisher of the cause." A similar communication was also received from Mr. Highmore, of Sherborne, who fully agreed in the importance and necessity of the meeting, and promising a "renewal of his subscription, that the Union Medical Officers, by united efforts, may obtain redress of their grievances, by being properly recognized and required."

A communication from Mr. Collins, of Kenton, informed the Committee that the medical officers of St. Thomas's, Exeter, had memorialized the Guardians on the subject of their grievances, which had been laid before a Committee appointed to consider and report upon its merits; but that the memorialists had succeeded in obtaining only a trifling increase of salary for the medical officers attached to two or three remote parishes, out of forty-nine composing the Union.

Mr. Sawyer, of Alfriston, wrote, informing the Committee that he was connected with two Unions, and states as follows:—"That, having remonstrated with the Guardians of the West Fife Union on the inadequacy of 3s. per case, as a remuneration for my services, the mileage being three on an average, and in consequence of another Medical Officer of the Union declining to attend any longer, the Workhouse containing 100 inmates, at a salary of £10 per annum, the Guardians have advertised the whole Union, including the Workhouse, at £3 less than the present inadequate salaries; I do not think, however, they will succeed in getting any one who will have the hardihood to undertake duties it is physically impossible to perform. But it proves the

necessity of our urging upon the Legislature and the Poor Law Board our right to hold these appointments permanently, and the justice of being fairly remunerated for very onerous duties."

A strong letter was received by the Secretary of the National Institute, from Mr. Gibson, of Ulverstone, one of the Members of Council, in which he states, "that, although unconnected with any Poor-Law appointment, I highly approve and appreciate the motives which have actuated the Union Surgeons in endeavouring to obtain from the Legislature a redress of their grievances; the present system is most oppressive and injurious to the medical profession and to the poor, also a great calamity and dishonour to a Christian country, as well as being based upon a principal of false economy."

The following gentlemen attended the meeting as delegates:—Mr. Wm. Ingle, on behalf of the medical officers of the Ashby-de-la-Zouch Union; Mr. Watkins, of the Towcester Union; Mr. Jordison and Dr. Corbet, as representatives of the Medico-Chirurgical Association, for the Billericay, Romford, and Orsett Unions.

Several other letters were also received from different parts of the country, the writers testifying their approbation of the course pursued by the Committee, and a general interest in the proceedings of the Convention.

Enough has been said to manifest the deep and diffused feeling entertained generally by Poor-Law Medical Officers on the subject of their grievances, which affords fresh stimulus for action on the part of the Committee; but to enable them to labour effectually, the sins of war—MONEY, must not be forgotten by those for whose benefit and relief such exertions are being made. As respects the expenses hitherto incurred, it is due to the Council of the National Institute to state, that owing to their kind consideration, a great item of expense for rooms has been avoided,—all along most eligible offices have been gratuitously afforded for the use of the Committee of Union Surgeons. Last year, the Council obligingly provided the spacious room for the public meeting, and they generously did so again on the 19th instant.

NOTES ON AMERICA: ITS MEDICAL SCHOOLS AND ESTABLISHMENTS.*

By EDWARD HUMPAGE, Esq., M.R.C.S., Bristol.

The clinical lectures of Professor Mott† are delivered every Saturday, from eleven until one o'clock, the cases are taken indiscriminately as they arise, and are furnished of course, from the humbler ranks; occasionally a fair lady appeared in silk and feathers, but as dress in the United States is no criterion of station, advice was given and thankfully accepted. On this occasion, (Nov. 4th.) an interesting case of hypertrophy of the left ventricle in a boy, suggested some valuable remarks on the utility of issues, in the curative effects of which, Dr. Mott places much reliance; he quoted the late Baron Larrey, whose pupil he was, and for whose surgical opinion he entertained the highest respect. It appears the Baron had great confidence in the effect of issues, and believed that they often removed the *materies morbi*, or any chronic ailments.

The next case was one of scrofulous disease of the

* Continued from page 106.

† In the previous communication there was an accidental error,—viz., *malar bone* instead of *maxillary bone*.

hip-joint, for which occasional leeching over Ponpart's ligament was advised; to be followed by counter-irritation, combining this local treatment with perfect rest, and the exhibition of hydriodate of potass with sarsaparilla. Following this was a case of psosas abscess, of which the prognosis was unfavourable, as the source of the disease appeared to be in the bodies of the lumbar vertebræ. Next came a case of talipes; and "Here, gentlemen," said the worthy professor, "we must shorten the ropes." I hoped to have seen the division of the tendons, but it was delayed for some more convenient opportunity.

A case of uterine irritation called forth some remarks on the great tendency in the present day, both in the old world and the new, to *specialities* in disease. Dr. Mott does not believe in all that is said on this subject, and thinks this view is often made the medium of quackery: hence, "We hear," said he, "of Dr. A. as the man who understands uterine affections; Dr. B. who cures the eyes; Dr. C. for the urethra; and Dr. D. for the more ignoble, but not less important, diseases of the rectum!"

There were several cases of syphilis in the form of eruptions, for which iodine and sarsaparilla were used, but most usually the chief reliance is on minute doses of bichloride of mercury. A case of caries of the ossa nasi presented itself. The patient was a woman. The skin of the nose was sound, but pus was distinguishable. She had no idea of the syphilitic origin of the disease, and this fact led the Professor to remark that we should always be careful not to say too much "on delicate subjects;" cure your patient, but do not embitter home by any suspicions as to conjugal fidelity. "I did not open this little abscess of the nose, gentlemen," said he, when the patient had left, "because she will have a sore there long enough, and I did not choose to begin it with the lancet, as blame is often attached to the surgeon for making wounds he cannot heal. Mind this, gentlemen, when you get into practice; it is worth recollecting."

A case of bronchial irritation suggested some remarks on remedies, mineral and vegetable. There is at present a great outcry in the States about the abuse of mineral remedies in chronic diseases, and a sect has arisen advocating the *sole* use of vegetable remedies,* and vapour baths. These persons call themselves Thompsonian physicians, not one half of them knowing, perhaps, whether the liver is on the right, or the left, side of the body. The profession set their faces against these persons who, nevertheless, do an enormous business, and frequently beat the regular practitioner out of the field. Dr. Mott commented very *severely* and *justly* on the want of legal redress in these matters, in the State of New York, for at present no law requires any professional education for the practice of medicine or surgery, in that part of the United States, and many men doing a practice of 5000 dollars a year, (about £1000,) had commenced their career as mere retailers of drugs, or as veterinary surgeons. This

state of things leads to all kinds of quackery, and greatly lowers the character of medical men, or, as they are always called—"Doctors." The public there have not half the respect for the profession which is seen here, nor have the honest respectable men in the profession there that influence with the public which they deserve, and ought to exercise.

As a remedy for the cough of chronic bronchitis, Dr. Mott says there is no place in the world equal to the Island of Malta, where there is always an equable and moderate temperature, very favourable to mucous exhalation. Dr. Mott says he cures pertussis easily with the following combination:—

R. Olei Essent. Amygdal. Amar., m. viij.; Extr. Belladonnæ, gr. vj.; Tinct. Camphoræ Comp., oz. iss.; Misturæ Acaciæ, oz. iiss. M. Capiat cochl. parv. j. vel. ij. ter die.

(To be continued.)

NOTES FROM A PRACTITIONER'S DAY BOOK.*

DISLOCATION OF THE HUMERUS.

What was the nature of the lesion in the following case? Was it a partial dislocation of the head of the humerus upon the edge of the glenoid fossa? I had gone on a visit to some friends who had taken country lodgings at a farm-house; a thunder storm came on suddenly, and was followed by a heavy rain, which, threatening to be of some hours' duration, I agreed to remain supper, and to occupy a bed in the house. In the kitchen there was pointed out to me a boy, who sat with his arm in a sling, and his coat thrown loosely over his back. A week previous he had received a blow on the shoulder from a fall, and had been unable to use the arm ever since. This lad was the patient of another medical man, and I felt no inclination to interfere; he had been told there was nothing out nor broken, and had been directed to rub the part with a stimulating liniment. After some trouble my friends teased me into examining the boy. I could notice no difference in the form of the two shoulders; but the boy complained of pain whenever I attempted to move the arm, and especially when I drew the elbow from the side. Making extension on the humerus downwards, and placing my hand in the axilla, I pressed the head of the bone outwards; while, executing this movement, I fancied that I felt something slip in the joint, but if it was so, the movement was so trifling, that I cannot speak with any degree of certainty. After some further examination, I thought I could detect nothing wrong, and only felt too happy to confirm the opinion which had been previously given, and to recommend a continuance of the same treatment, as it was the best under the circumstances. The next morning, on my way out of the house, I encountered the lad, and merely by way of saying something civil, I asked him how his shoulder was. To my horror, (for I thought of the breach in professional etiquette,) he waved his arm over his head, and said I had quite cured him.

* The chief of these are the Lobelia inflata, capsicum, and several bitter and aromatic plants.

* Continued from page 712 of last volume.

INFLAMMATION OF THE CRANIAL BONES.

A gentleman was thrown from his gig, and received a compound fracture of the os frontis, requiring the removal of several small spiculæ of bone. A long time elapsed before the wound healed, and even, when at length, it did so, he remained liable to renewed attacks of inflammation and exfoliation. I first became acquainted with him soon after he had undergone one of these accidents. A sinus on the middle of the forehead led obliquely down to a portion of exposed bone, which might be grasped with a pair of forceps, but was not loose enough to be removed. I directed him frequently to introduce a piece of lint, soaked in nitric acid lotion, and to allow it to remain in contact with the bone. After several months' continuance of this treatment, the bone could no longer be felt, and the sinus now readily healed.

Since the time of the accident, he had always been subject to chronic pains about the forehead, sometimes very severe, and sometimes trifling; but these had been greatly relieved by the iodide of potassium which I had prescribed. During my absence, however, he once fell into the hands of another practitioner, who, imagining the case to be one of anæmic headache, ordered the tinctura ferri muriatis, together with the use of the cold shower bath. The immediate consequence of wetting the hair was a renewed attack of inflammation in the cranial bones; my patient was himself confident that this was the exciting cause, as he now remembered that a previous attack had been brought on in the same manner. But little was done at first, though for many days he was suffering very severely from pain over the left brow; this partook somewhat of a neuralgic character, from the circumstance of the first branch of the fifth nerve being compressed, as I supposed, in the supra-orbital notch by thickened periosteum. The left side of the frontal bone was very sensitive to the least pressure, and the parts over it exhibited a slight degree of puffy swelling; the constitutional disturbance was not greater than might be accounted for by the intense sufferings, which allowed him to get but little sleep. He soon found it necessary to confine himself to his bed, for the least mental or bodily exertion, or exposure of the eyes to a bright light, increased his agony in an intolerable degree. Being now consulted, I ordered a large blister to be applied over the forehead, and the sore produced was kept open for more than a fortnight, with alternating dressings of a vesicating, and of the mercurial, ointment. At the same time, I administered internally the iodide of mercury,—half a grain at first, being gradually increased to a grain and a half every four hours. Many days elapsed before any improvement was apparent, and he always require a large dose of opium at night before he could obtain any rest. When the amendment commenced, it was very gradually, though steadily progressive, and as long a period as five weeks elapsed before he was able to leave his chamber. Before he did so, however, I substituted for the iodide of mercury, the iodide of potassium, giving it in two-grain doses thrice daily in solution. No exfoliation occurred on this occasion, and very little thickening of the periosteum remained; whilst he continued pretty free from pain for some time afterwards, suffering only occasionally, and in a very slight degree.

Although I prescribed the iodide of mercury in this instance, I do not feel disposed to do so on any future occasion. The remedy was attended with considerable inconvenience, frequently causing severe griping pains, and always requiring full doses of opium to prevent its acting on the bowels. Had I a similar case to treat, with my present experience, I should endeavour to act gently on the gums with calomel and opium, and, at the same time, administer the iodide of potassium in solution.

THE DIAGNOSTIC VALUE OF PAIN.

Pain is a very uncertain indication of the seat of disease. I remember reading somewhere of a gentleman who suffered from a very severe pain in the hip, and was immediately relieved by the excision of a part of the great toe nail, which had become inverted, and had produced ulceration. Sir Benjamin Brodie relates the instance of a gentleman who was awakened during the night by a sharp pain in the heel, which forced him to get up and walk about the room in agony. Whilst doing so, the condition of his stomach was indicated by an extremely acid eructation, and he took a dose of carbonated soda; this gave almost instant relief. The pain in the heel, in conjunction with an aced state of the stomach, requiring an alkali for its cure, afterwards occurred frequently enough to convince him of their relation. I was in the habit of introducing the catheter into a little girl's Eustachian tube, and when it rested upon the cartilage, I asked her where she felt it; she invariably pointed to a spot below the clavicle. I attended a man with severe rheumatic pericarditis, in whom the most severe pain evidently connected with the state of the heart, was referred to the left iliac fossa, and yet I had no reason to believe that there was any disease in this situation. The pain caused by the passage of a gall-stone is complained of in the epigastrium, not towards the right side; whilst that, which under certain circumstances is experienced during the passage of an evacuation through the ileo-cæcal valve, is situated in the median line, not in the right iliac fossa. I was once suffering from a small ulcer under the thumb-nail, which followed a dissection wound. In addition to the severe lancinating pain which I experienced in this situation, there was another, equally acute, upon the metacarpo-phalangeal joint of the index finger, where there was really nothing the matter. Every practitioner is acquainted with instances in which a pain, dependent upon a disordered liver, is experienced about the right shoulder, and another, connected with a diseased heart, which is referred to the insertion of the left pectoralis muscle.

COLIN ARNECAPUE.

(To be continued.)

POOR-LAW MEDICAL RELIEF AND MEDICAL REFORM.

TO THE POOR-LAW SURGEONS OF ENGLAND AND WALES.

Gentlemen,—I beg permission to address a few words, and to observe to you, that many of the circumstances stated at the meeting of Poor-Law Surgeons on Monday last, gave me great concern; not only that they did occur, but that under the present state of medical affairs

there was a presumed necessity for submitting to them until Parliament, and the Government would cause them to be corrected.

Expressing my own individual feelings and sentiments merely, I would never submit to the humiliations and indignities which in many cases are inflicted on medical men in relation to pauper practice, but would be content with a private practice, however small, if it would afford me and my family a maintenance in decent comfort; and if it was insufficient for that purpose, I would flee away, and take refuge in some Australasian region, where, taking spade in hand, or applying it to the plough, I would raise wherewith to subsist in the enjoyment of tranquillity of mind, and health of body, in an independence, rude though it might be.

In my humble opinion, however, there is no necessity for such an alternative, if the Poor-Law Surgeons would take a wide and comprehensive, instead of a narrow, view of their position; for I feel thoroughly assured that the Poor-Law Medical Officers are not sufficiently aware of the fact, that the real and ultimate cause, the fountain-head of all their grievances, is the disorganized state of the public affairs of the medical profession itself, which is almost a chaos, becoming daily worse and worse, if possible, from the creeping and crawling, and intruding of ignorant, incompetent, and unauthorized men into medical practice.

The attention of the Poor-Law Surgeons is too exclusively absorbed in the contemplation of those grievances which more immediately beset them; and they do not, in my humble opinion, look beyond them to the original cause. At the same time, therefore, that they ask to be relieved of the evils which more especially oppress them, they should seek Medical Reform, *as a whole*, and should earnestly pray for it in the spirit, at least, of the resolution which was proposed, and was not submitted to the meeting on Monday, but is subjoined to this communication.

If the parties most immediately concerned should fear that the especial cause of the Poor-Law Surgeons would be damaged or at least endangered by praying for the reform of the whole profession, I would say, that our great fault all along has been the manifestation of a low and cowardly spirit. Why otherwise occur many of those things of which we heard at the meeting, and which, with the pleadings *ad misericordiam* disgrace us amongst ourselves, and lower us in the estimation of the public and of Parliament?

At the same time, therefore, that we seek redress for the grievances of which we so loudly complain, let us exert ourselves by all the means in our power to obtain the reform of the whole profession by some legislative measure, grounded on the evidence taken before the Parliamentary Committee of the last Session, as the only effectual cure for the social as well as professional evils which afflict all branches of the profession, the Poor-Law Surgeons more especially.

I have the honour to remain, Gentlemen,

Your very faithful servant,

THOMAS MARTIN.

Reigate, February 24, 1849.

Resolution suggested by James Wyld, Esq., M.P.

"That this meeting, while especially advocating the claims of the Poor-Law Medical Officers to relief as far as practicable from the numerous and oppressive grievances which peculiarly afflict themselves, is fully aware of the fact, that manifold, dangerous and daily-increasing evils are entailed upon the community by the anomalous

state of the laws affecting the medical profession generally.

"That the evidence taken before the Parliamentary Committee bears ample testimony to the correctness of the above declaration, all the witnesses coinciding in the opinion that a revision of these laws is absolutely necessary, as much for the advantage of the public interests as for the peace and tranquillity of the medical profession.

"That this meeting therefore expresses an anxious desire that the Government will cause a Bill for the amendment of the laws affecting the medical profession, and for regulating medical practice in the United Kingdom, to be laid before Parliament with as little delay as possible, and that it be based upon the evidence taken before the Parliamentary Committee.

"And this meeting ventures still further to express a hope, that the Government and the Legislature, in consideration of the important interests involved in the matter, may be induced to legislate forthwith upon the subject, so that an effective law may be enacted during the present Session of Parliament."

CHLORIDE OF OLEFIANT GAS AS AN ANÆSTHETIC.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

A few days after the publication of the last number of the *Provincial Medical and Surgical Journal*, Dr. Snow did me the favour of forwarding to me a pamphlet "On Narcotism by the Inhalation of Vapours;" and from Dr. Simpson I yesterday received a communication on the subject of my note to you, published in the *Journal*, by which I learn that what I had supposed to be new æsthetics had been already spoken of. Dr. Snow relates experiments he has performed on three mice, with the Dutch oil, and Dr. Simpson informed me that he has made experiments with both the substances which I mentioned, and that in the *Monthly Journal*, published eight or ten months ago, he described the anæsthetic powers of Dutch liquid. Had I been in the least aware that such had been done, of course I should not have announced these agents as new; but the facts having appeared in two journals which I never see, accounts for my ignorance of what had been done. As there is no date beyond that of 1848 to Dr. Snow's pamphlet, I am not aware of the precise date of his experiments, which originally appeared in the *Medical Gazette*, but as he alludes to those of Dr. Simpson, it must have been some time after his.

I may mention that with coal gas my experiments were made in last July; with the Dutch liquid it was not until near the close of the year, though it was one of the substances I had long before put down for trial, but having several others at hand, and there being some difficulty in procuring the fluid, it was postponed until others had been disposed of. So far as I am individually concerned, it was to me the discovery of new agents, but these gentlemen having publicly named them, have a full claim to public priority, which I most cheerfully concede.

Dr. Simpson's paper I have not seen, not having been able yet to obtain the Journal in which it appeared. I therefore take my knowledge of his trials with Dutch oil from what Dr. Snow says, in his quotation, which is, "that its vapour, when inhaled, causes so great irritation of the throat, that few persons can persevere in inhaling it long enough to produce anæsthesia, but that he had seen it persevered with until this state was induced." While out of the three mice upon which Dr. Snow experimented, two died, and the third was *not* made insensible, as he supposes from the irritating nature of the vapour, an account from these gentlemen of so discouraging a character, as would certainly deter any one from using the fluid in practice. Indeed, had I seen these reports of its effects, in the hands of two gentlemen of such great experience in the action of anæsthetic agents, I should have considered them so dangerous as not to justify or render necessary any further experiments with it.

But such has certainly not been the case in my hands. I find it to be the least irritating of any anæsthetic agent which I have tried, and further investigation justifies me in repeating all I said in my notice of it. I have tried it upon many dogs and rats, young and old, in large and small doses; in no one instance have I seen any irritation caused by it, nor any repugnance to its inhalation. The animal quickly and pleasantly passes into a profound state of insensibility, and remains so. As I stated, a more death-like condition is recovered from than after chloroform, and in every instance the animals have quickly rallied and remained well, except in one where I intentionally destroyed it to observe the *post-mortem* appearances. Having ascertained the effects upon animals, I inhaled it myself, and found the action not only not disagreeable, but perfectly agreeable in every respect. My assistant, Mr. Beaumont, has taken it once, and my pupil, Mr. Morham, has taken it twice, on two successive evenings; both were rendered as insensible as is either necessary or safe for the performance of any operation whatever, or by whatever agent induced. In neither was there the least irritation; in fact both begged for more before becoming insensible; and when rallying from this condition, and both were immediately well. The latter of the two, who has three times inhaled chloroform, declares the effect of the Dutch oil, both at the time of inhaling and subsequently, to be far more pleasant than that of chloroform. I last night gave the Dutch oil to four gentlemen: in all it answered admirably, all had previously taken chloroform, and they were unanimous in declaring the oil to be more effectual, pleasant, and speedy, with less uncomfortable feelings afterwards. I repeat, then, it is an agent likely to be usefully employed, and I can only account for the unpleasant consequences in the experiments of Dr. Simpson and Dr. Snow, by the supposition that the preparations they used were impure, which I imagine Dr. Simpson now would agree to, inasmuch as in the letter with which he has favoured me he says, after this notice he obtained "some more pure, and got effects exactly like chloroform." There are other substances which I have tried the effects of, and found to possess anæsthetic power, one indeed far more

powerful than any I have yet seen named, but lest I should again find myself anticipated, I abstain from naming them until the paper in which the experiments are related, appears in the "Transactions" of the Association.

I am, Sir,

Yours faithfully,

THOMAS NUNNELEY.

Leeds, March 2, 1849.

P.S. Dr. Simpson informs me, in objecting to Dutch oil, "that it is too expensive, (far more so than chloroform,) and it is very difficult to purify." I am not a practical chemist sufficient to determine this question, but the constitution of the fluid, and the formula for its preparation, would not lead me to form such an opinion. Neither carburetted hydrogen nor chlorine are at all expensive gases, and the process for combining them is not a complex one. That which I obtained at two different times appears to have been pure, the price charged was very much less than I was charged for chloroform when it was first introduced, at least 30 per cent. less, and if the price of chloroform has fallen considerably now that it is an article regularly made, there is no reason to suppose that of Dutch oil would not do so in the same proportion. This Mr. Bullock has promised to calculate, and inform me of.

NEW ANÆSTHETICS.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

Having observed in your valuable Journal of the 21st instant, a letter written by Mr. Nunneley, of Leeds, from which it may be inferred, that he is the discoverer of a new anæsthetic agent, in the use of the hydrochlorate of the chloride of acetylene, as possessing all the good qualities of chloroform, and being in a great measure devoid of those of a contrary nature, I deem it a matter of justice to myself, to state that, in December last, I instituted a series of experiments on several of the organic compounds, and among these on the above-mentioned agent. I then found it to possess most of the good properties which Mr. Nunneley has assigned to it, being sweet in taste and pleasant in flavour, and of which but a small portion is required to produce its soporific influence. It may also be kept up for a considerable time with impunity, and the recovery of the patient be tranquil, safe, and speedy. The favourable specific gravity and harmlessness of its action, together with other pre-eminent peculiarities, led me to predict that it would become ere long one of our safest and best anæsthetic agents.

It would be superfluous in me now to endeavour to claim originality in the discovery, but I may affirm that I had not the slightest knowledge that Mr. Nunneley was pursuing any inquiries on the subject when I turned my attention to it at the end of last year, nor when I mentioned it to Dr. Hobson, of Leeds, on the evening of Wednesday, the 7th of February, which was previously to the publication of

Mr. Nunneley's announcement. I then pointed out to Dr. Hobson, the predominating properties which Mr. Nunneley has ascribed to this agent, as the accompanying letter proves.

I need not to enter into an elaborate detail of its composition or characters, as Mr. Nunneley has with his usual talent and ability there depicted. As respects myself, however, I beg to hand you the letter from Dr. Hobson, in confirmation of what I have advanced. This I shall be obliged by your inserting along with mine in your next Journal; and I may add, that if Mr. Nunneley's publication had not made its appearance at the time it did, I should have called your attention to the point in question in a few days, with an elaborate detail.

I remain, Sir,

Yours obliged and respectfully,
RICHARD OASTLER JOHNSTONE.

Willow Cottage, Bramley,

Feb. 28, 1849.

[It is scarcely necessary for us to observe, that Dr. Hobson's letter fully confirms Mr. Johnston's statement.—Ed.]

Medical Intelligence.

LIGHT COAL-NAPHTHA AS AN ANÆSTHETIC.

We are informed by Professor Simpson that he has of late been using "Light Coal-Naphtla" as an anæsthetic, and finds it perfectly successful. It has one, but only one, advantage over chloroform—its cheapness—costing only one penny per ounce; but its savour is not by any means so agreeable.

IMPORTANT MEDICAL DECISION IN THE SMALL DEBTS' COURT.

THE MASTER AND WARDENS OF THE APOTHECARIES' COMPANY v. LOBO.

The action was instituted, we believe, at the instance of the Medical Protection Society, but the actual plaintiffs in the case were the *Master and Wardens of the Apothecaries' Company*, for the reason, that the statue under which the action was brought recognizes no other proper plaintiff. The effect of the decision is to bring the case of the penalties of unlicensed practitioners, among whom *all unlicensed practitioners, including chemists, who compound drugs upon prescriptions, whether their own or the prescriptions of authorized practitioners*, are included, within the jurisdiction of the Small Debts' Courts, thus rendering recoverable, at the risk of two or three pounds, penalties, all former attempts to recover which involved an expense of more than £350 upon each action. The law, therefore, which has hitherto been a dead letter, on account of the enormous expense necessary to put it in motion, will now, we have little doubt, be rigidly and universally enforced.—From the *Standard*.

APPOINTMENT.

R. Lloyd Williams, M.D., F.R.C.S., has been appointed visiting Physician to the North Wales Hospital for the Insane.

ROYAL COLLEGE OF PHYSICIANS

HARVEIAN ORATION.

Dr. Badeley, of Chelmsford, is appointed to deliver the *Harveian Oration* before the Royal College of Physicians, on the 25th of June next.

ROYAL COLLEGE OF SURGEONS.

Gentlemen admitted Members on Friday, Feb. 23 :—H. Chawner; J. Nash; S. J. A. Palmer; G. F. Ree; T. Mather; J. W. W. James; E. G. Goulden; C. J. Bennetts; F. H. Orvis; G. Betts.

Friday, March 2 :—P. Allen; G. F. Gwyn; J. G. Gibbs; J. Smith; W. H. Johnson; W. R. Hayne; W. Cooke.

SOCIETY OF APOTHECARIES.

Gentlemen admitted Licentiates Thursday, February 15th :—William Bratt, Stratford-on-Avon; John Hall Bywater, Knottingley.

Thursday, March 1st :—James Williams, Holywell; Richard Wilson, Poulton le Fylde; Thomas Henry Newsam, Leeds.

OBITUARY.

Died, in September last, at Malta, where he was residing for the benefit of his health, James Carson, Esq., M.B., Senior Physician to the Northern Hospital, Liverpool.

January 29th, Wm. Peck, Esq., Surgeon, Kimbolton, Huntingdonshire.

TO CORRESPONDENTS.

Communications have been received from Dr. Copeman; Mr. Martin; Dr. S. Edwards; Mr. Humphry; the Birmingham Pathological Society; Mr. T. B. Smithies; Dr. Oke, a Member; Mr. Humpage; Dr. Ballard; Dr. Heaton; Mr. R. O. Johnstone; Mr. Bottomley; Mr. T. W. Crosse.

PROVINCIAL MEDICAL & SURGICAL JOURNAL.

A COURSE OF LECTURES ON SURGERY,

DELIVERED IN THE

MEDICAL SCHOOL OF CAMBRIDGE.

By GEORGE MURRAY HUMPHRY, Esq., Downing College, Surgeon to Addenbrooke's Hospital.

LECTURE V.

EFFUSIONS OF SERUM AND LYMPH.

Effects of Inflammation; the Order in which they occur varies according to the Vitality and Peculiarity of the Tissue affected, and the Peculiarity of the Inflammation: Effused Serum generally disappears with the Inflammation; occasionally is persistent; sometimes is the only Symptom, as in Hydrocele, Hydrothorax, Hydrops Articulii; Treatment: Effusion of Lymph, its Organization; rarely becomes organized on the Surface of Skin or Mucous Membrane; the Structure into which it is converted; shows Signs of imperfect Assimilation of Fibrin by its Contraction, which, as well as the Disposition to contract when stretched, ceases after a Time; Strictures; Cicatrices; Contractions of Joints; the Force of Contraction proportionate to the Force of Organization of the Fibrin, from which the new Structure is formed; false Membranes liable to same Diseases as other Parts,—to calcareous Degeneration; undergo various other Changes, according to the Movements and assimilative Influences of surrounding Parts—in Bursæ, Joints, serous Cavities; Melon-seed-like bodies; loose Cartilages. Insidious Lymph-formations; Treatment by Mercury, Stimulants, Pressure, Bougies; their Mode of Action; Excision.

The injurious effects of inflammation upon the organ in which it is seated consist, first, in the effusion of new products, serum, lymph, and pus, into the interstices of its substance; and, secondly, in the alteration and destruction of its texture by atrophy, softening, interstitial absorption, ulceration, and mortification. In the ordinary course of things these changes take place nearly in the order above enumerated, the effusion of serum being the attendant on the mildest, and mortification the result of the severest, forms of the disease. This order is, however, liable to be interrupted by numerous causes, such as variations in the strength of the patient, and the vital energy of the part affected. I have before mentioned that in old and feeble persons a slight amount of inflammation is quickly followed by ulceration and mortification. The vitality of the textures is with difficulty maintained in such persons

under ordinary circumstances, and gives way altogether under the disturbing agency of inflammation. Compare the inflammation of the healthy and robust man with that in the lower extremities of the old person, where the nutritive and reparative forces are failing, and the circulation is impaired by the diseased condition of the great arterial trunks. In the former the inflammation, acute and painful in its progress, is attended by the formation of lymph and pus, ulceration occurs only to a sufficient extent to open the abscess, the contents of which are well elaborated and quickly discharged, granulations follow, and cicatrization takes place without much loss of time; whereas, in the extremities of the aged and infirm, the inflammation, consequent probably on some slight provocation, such as a little scratch or bruise, does not amount to any great severity, and the disease presents few of the ordinary characters of an acute affection; but it is disastrous in its effects, for the textures quickly give way under it, ulcers soon occur, spreading, and difficult to heal, and mortification commences. The destructive progress of the disease depends, too, not merely on the disposition of parts to fall a prey to ulceration and mortification where the inflammation was first excited, but in the facility with which the inflammation spreads among the adjacent structures; they offer but little resistance to its progress, so that it runs from point to point, carrying desolation with it, and terminating, for the most part, only with the destruction of the limb or life of the patient. So fatal in its results may be the slightest disturbing cause where the processes of nutrition are thus feebly conducted.

Corresponding results occur also generally in the textures and parts of the body to which the supply of vessels is most scanty, and in which the vital energies are least active, such as bone, tendinous and fibrous textures, in all of which inflammation is frequently followed by mortification. In the lower extremities inflammation is more destructive than in the upper, and in both than in parts nearer to the centre of the circulation. There appears, however, to be some peculiarity in certain textures which predisposes them to one or other of the effects of inflammation; thus mucous membranes and the skin are very prone to ulceration, and serous membranes to the formation of lymph, although the former are more vascular than the latter.

Much depends, also, upon the peculiar character of the inflammation itself. In chilblain the congestive stage is of long duration, and, if the inflammation

proceed beyond it, the next effect is commonly ulceration. Erysipelas sometimes produces mere scaling of the cuticle or effusion of serum beneath it, in the form of vesicles, or into the subcutaneous cellular tissue, causing œdema. In other cases it passes on quickly to suppuration and mortification, not only of the skin, but more particularly of the cellular tissue. In one form of specific disease—gonorrhœa, the inflammation often lingers for months, and produces only suppuration from the surface of the membrane; in another—syphilis, the ulcer is generally the earliest symptom. In boil, carbuncle, and the plague, the inflammation hurries over the early stages, and runs on quickly to the mortification of the parts affected. The varying effects of peculiar kinds of inflammation are illustrated also in small-pox, measles, scarlatina, and croup.

Under ordinary circumstances the earliest and least injurious effect of inflammation consists in the effusion of a preternatural quantity of serum into the interstices or upon the surface of the inflamed part; this takes place with facility proportionate to the looseness of structure of the organ affected, and the delicacy of the patient. A very slight inflammation of the face will cause such swelling, by effusion of serum into the loose tissue under the eyelids, as completely to alter the features; and you have, doubtless, observed the rapidity with which œdema follows inflammation occurring in feeble, delicate, emaciated persons.

When the inflammation subsides, this serum is commonly removed as readily and quickly as it had been effused; or a slight degree of pressure, or a gentle stimulus, will suffice to effect its resorption. Occasionally, however, it remains for a considerable time after the other evidences of inflammation have passed away, and its continuance indicates a weakened state of the part, or a debilitated condition of the patient. An œdematous fulness of the eyelids often remains for a long time after an attack of erysipelas of the face, and ceases only when the patient has recovered his health and strength. There are at the present time two instances of this œdema of the face after erysipelas among the out-patients; one in a delicate young woman, the other in a man much enfeebled by the attack of erysipelas, which occurred some months ago.

In some cases the persistence of œdema in the subcutaneous cellular tissue is the result of continued deep-seated inflammation in the limb. Perhaps there is an abscess beneath the fascia which time will more clearly reveal; there may be ulceration of the cartilages of a joint, or some disease of the bone. I remember a remarkable instance of this kind in a man who suffered under œdema of the upper extremity, chiefly about the elbow; for some time it constituted the only symptom, and could not be traced to any disease of vein or obstruction to the circulation. Other symptoms supervened requiring amputation of the limb; and we found that inflammation and necrosis of the medullary texture of the humerus had been the cause of the continued swelling of the arm.

This earliest and slightest effect of inflammation requires our further attention, inasmuch as it sometimes

exists alone, and constitutes the entire disease. This occurs more particularly in the serous cavities. Hydrocele is a good and familiar example of it. The swelling of hydrocele commonly takes place slowly and imperceptibly, is not attended with pain or other decided evidences of inflammation, and is inconvenient only from its bulk. We can at first scarcely believe that this slight painless affection,—this simplest of diseases, is the result of that same morbid process which gives rise to the formation of an acute abscess, and which sometimes brings speedy destruction to limb and life. Nevertheless a little reflection will convince us that these different effects are connected together by sufficient intermediate links to chain them to one common cause; and we shall find little difficulty in admitting the serum of hydrocele to be as much the product of inflammation as the pus of an acute abscess. In the first place hydrocele frequently occurs as the remnant of an acute inflammatory attack, during which the tunica vaginalis was distended with fluid, as in the common hernia humoralis, or epididymitis, where the swelling chiefly consists of serum effused into the cavity of the tunica vaginalis; the inflammation subsides, its other effects pass away, but the serum may remain, and form a hydrocele. Secondly, an examination of the interior of the sac, in most cases of hydrocele, furnishes additional evidences of the existence of inflammation, such as adhesions and thickening of the membrane from deposit of lymph, induration of the testicle, or epididymis, and so forth. The disease is not generally to be cured by the ordinary means employed to effect the removal of serum; counter-irritants and pressure usually fail. If the fluid be evacuated, it soon collects again, and we are obliged to resort to various means of exciting a more acute inflammation to cure that slight disease upon which the effusion depends. We inject an irritating fluid into the distended tunica vaginalis upon the same principle that we apply a blister to remove a chronic cutaneous affection. We excite a new inflammation, which cures the old one, and terminates by resolution; for you must know that it is not essential to obliterate the hydrocele cavity; the mere change produced by a certain amount of inflammation of its lining membrane is sufficient to cure the disease.

Effusion of serum sometimes takes place in the same insidious manner into the cavity of the pleura, and attracts attention by its pressure upon the lungs, the first symptom of its presence being not pain, but dyspnoea. The same affection of synovial cavities constitutes hydrops articuli, and these effusions into serous and synovial cavities are generally difficult of cure, in proportion to the slowness of the inflammation which induced them. So resistant are some of these cases to the modes of treatment usually adopted for the removal of serum, such as blisters, pressure, mercurial inunction, &c., that the same energetic proceeding which we employ for the treatment of hydrocele has been adopted in them, and the injection of a solution of iodine into the cavity of a joint, by exciting acute inflammation, is reported to have been occasionally successful in curing the chronic disorder. I do not recommend you to try this

summary proceeding, because I do not think the disease is sufficiently severe to warrant so dangerous and uncertain a remedy. Even in the tunica vaginalis, we cannot always regulate or control the inflammation excited by our injections; sometimes it is insufficient to effect a cure, at others it exceeds our wishes, and extends in a severe form to the epididymis or testicle. Much more should we apprehend danger to the joint, if not to the life of the patient, from the application of an irritating fluid to so susceptible a texture as the synovial membrane. We have sufficient experience of the destructive effects of acute synovitis to make us unwilling to adopt so decided a method of inducing it as the injection of an irritating fluid into the cavity of a joint.

Œdema from effusion of serum may result also from other causes besides inflammation, such as local or general obstruction to the circulation; general debility, when the blood is thin, and its fluid components pass with greater facility than natural through the walls of the capillary vessels, which, partaking of the general want of tone, do not sufficiently regulate the escape of their contents; and local debility, for instance, when the lower extremity has been long confined in splints, in consequence of fracture, and is at length freed from restraint, and allowed to hang down, the weakened vessels and tissues, are unable to bear the weight of the superincumbent column of blood, and œdema results, continuing sometimes for a long period, and forming a troublesome symptom for months after the injury.

In the progress of the inflammation some of the fibrin of the blood altered in the manner before described by the inflammatory process, passes with the serum through walls of the capillary vessels into the interstices of the adjacent tissues, where organization quickly commences. The fibrin or lymph, as it is often called, concretes into a more or less consistent clear jelly-like substance, in which exudation corpuscles, nearly resembling the white globules of the blood, are sometimes observed. These passing through the several stages of cell-formation, may become converted into tissue much after the same plan as that by which the embryonic structures were originally developed. At other times, and this is, perhaps, the more common mode, the fibrin becomes organized by a simpler process, similar to that which takes place in the coagulation of blood removed from the body; its particles are at once arranged into fibres, and these fibres unite into a tissue, without undergoing the more complex intermediate stage of cell-formation.

The fibrin, as well as the serum effused in inflammation, corresponds closely with that of the blood circulating through the inflamed part, having undergone very little change in its passage through the walls of the vessels. At first it is suspended in the serum, and when concentered, it presents an indistinctly fibrous or reticular structure, resembling that of the buffy coagulum formed out of the body, but more elaborate, in consequence of the more favourable situation for organization in which it is placed. A blister sometimes affords an opportunity of observing the exudation of fibrin in inflammation, and its coagulation

into a loose reticular structure, from which the serum is gradually expressed.

When the inflammatory fibrin or lymph is effused upon the surface of the body, as in the case of a blister, or upon the membranes which line the canals communicating with the surface, the process of organization never goes on to any great extent. The new product rarely obtains an organic connection with the skin, or a mucous membrane, or becomes traversed with vessels. It is soon dislodged, in consequence of the movements of the part, the formation and passage of its secretions, and other causes, and is separated from the body. Hence it is that adhesions of the opposed surfaces of canals opening upon the surface of the body are so rare, and, perhaps, never occur, without the previous destruction of the mucous membrane which lines them. The instances in which lymph is found remaining, even for a short time, upon the surface of a mucous membrane, are few. It is sometimes seen in the trachea, more particularly in croup, when the effusion takes place rapidly, and the new product is expectorated sooner or later if the child lives. The lining membrane of the uterus, after puerperal inflammation, is sometimes found to be coated with lymph, which is not much disturbed, either by the slight movements of the organ, or by the scanty secretion from its surface. In the ureters, where the secretion of the kidneys trickles slowly down, and in the bladder, where it gradually collects, and is gently evacuated, the lining membrane is sometimes found covered with tubes or flakes of lymph, though it may be a question whether they become organised even here. In this specimen the coating of lymph extends through the urethra, and in this the canal of the ureter is completely obliterated; I suppose that in this latter instance lymph had become organized and filled up the tube, but it is associated with such extensive disease of kidney, that the formation of urine on that side had probably been quite suspended for a considerable time. The small amount of secretion furnished by the mucous membrane of the bladder and ureters, which has no special glandular apparatus, is another circumstance rendering it more likely to become the seat of deposits of lymph, than the membrane lining the other excretory passages.

In the closed cavities, more particularly in those lined by serous membranes, and in the interstices of the textures, the effused lymph becomes organised, connected with the structures upon or among which it lies, and supplied with blood-vessels, which may be discovered in it after twenty-four or forty-eight hours. The mode in which these vessels are formed is not quite certain, but it is on the whole most probable that they, as well as blood contained in them, are the result of developmental processes taking place in the lymph, similar to those by which the vessels are first formed in embryonic tissues, and that they obtain a connection with the vessels of surrounding parts by the same mysterious power as that which enables them to unite together and form a plexus in the new medium. This is, I think, a more probable view of the mode of formation of vessels in new structures, than that which attributes them to the elongation and projection into the new

tissues of the adjacent capillary tubes. For the further exposition of this subject, however, I must refer you to the more particular accounts detailed in treatises on physiology.

The structure into which the lymph is ultimately converted under ordinary circumstances, is one of a simple kind, more or less resembling the common areolar or fibrous tissues; but it never attains to so great perfection of organization; it is never so soft, fine, and elastic; it is more opaque, and its component fibres are less distinct and regular in their arrangement.

It presents also another evidence of imperfect organization, and of the incomplete assimilation of the fibrin from which it is formed in its disposition to contract. This lasts for a considerable period after its formation, and gives rise to some of the most troublesome of the after effects of inflammation. It is by the gradual contraction of the lymph effused during inflammation into the substance of mucous membranes and submucous tissues lining the various ducts and canals that the greater number of strictures are produced. I say that strictures are occasioned by the contraction of lymph effused into the *substance* of mucous membranes, because, as I just explained to you, the lymph shed upon their *surfaces* very rarely remains for a sufficient length of time to acquire an organic connection with them. This property of the lymph is often not manifested till the inflammation which gave rise to the effusion has subsided, so that the active symptoms of the inflammation had generally passed away before the indications of stricture are observed.

It is rather a remarkable fact, and not very easily explained, that these strictures from effusion of lymph, or simple strictures as they are called, rarely occur except near the orifices of canals where the mucous membrane is surrounded by the striped fibres of voluntary muscles, or by these blended with unstriped fibres. I never saw, and do not remember to have read of a case of *simple* stricture of the alimentary canal in the interval between the upper end of the œsophagus and the sigmoid flexure of the colon, and suspect that it rarely occurs in the latter situation, except in connection with stricture of the lower part of the rectum. Simple strictures of the trachea and bronchi of the gall ducts, ureters, and ducts of the salivary and other glands are also exceedingly rare.

The disposition to contract continues for a certain time, and then ceases spontaneously, the new structure becoming gradually more assimilated to common areolar tissue in its properties and physical characters. So that if the contraction can by any means be prevented till that period has arrived, this evil consequence may be prevented altogether; and if the new structure be stretched after that period has elapsed in such a manner as to avoid the recurrence of inflammation, I believe I am right in saying that it will not resume its former contracted state. This specimen is a good illustration of the fact, that the narrowing of a tube from stricture goes on for a certain time only, and that the calibre of the tube at the strictured part may remain the same for a great number of years. It is the upper part of the œsophagus of a woman in whom

difficulty of deglutition had existed for 40 years. During the whole of that time she had been unable to swallow the smallest particle of solid food; even the fluids upon which she was supported were obliged to be made thin in order to pass the obstruction; on one occasion she was nearly choked by a gooseberry pip which accidentally reached the pharynx, and which was returned after causing her much suffering. Not long after the commencement of her illness she was examined by Sir Astley Cooper, who discovered a stricture of the œsophagus and gave an unfavourable opinion of the case. You see that the only trace of disease is the narrowing of the tube and a slight opacity of the lining membrane, with a few firm threads surrounding it, the shrunken remains, no doubt, of lymph effused long ago. How trifling a structural alteration in comparison with duration and importance of the symptoms occasioned by it: and how easily, in all probability, could the remedy have been applied and the stricture dilated had the precise nature of the case been understood at an earlier period.

The movements of joints are frequently impeded by the contraction of lymph effused into the substance of their capsules. This is particularly observed in the shoulder joint, and is a very frequent consequence of bruises from falls upon the shoulder; the capsule, which is very loose in order to permit the free movements of the joint, and strong to prevent its dislocation, becomes contracted in consequence of the effusion of lymph into its substance and upon its surface, and this takes place chiefly at the lower part of the joint, from the arm being kept against the side and from the capsule being thickest in that situation, so that when the active symptoms have subsided the patient is unable to raise the elbow; the deltoid wastes from disuse, and the flattening of the shoulder so produced, together with the continued inability to move the joint gives rise to the apprehension that some dislocation or fracture has occurred and been overlooked. In process of time, by use of the arm and stretching of the capsule, the movements of the joints may in a great measure be regained. These cases often fall into the hands of quacks, who proceed in a more summary manner. They declare that the bone is out of place and make forcible extension for the purpose of reducing it. By so doing they stretch the contracted capsule, and it may happen that the patient recovers the use of his arm in a short time, but I have frequently known severe inflammation of the joint excited by these rough proceedings.

The contractions of cicatrices going on for some time after ulcers have healed and wounds have united, is, in like manner, due to the continuance of this property in the imperfectly-assimilated fibrin of which they are composed. By its constant operation it becomes a very powerful force, overcoming the muscles and bending even the solid parts of the frame. It continues only for a certain time. The cicatrix ceases to diminish in size a few months after the ulcer has healed; if its contraction can by any means be prevented taking place till that time it will never occur at all, and if the cicatrix be stretched after that period without injury to its texture, I believe that it will not

return to its former state. The lad whom you have seen in the hospital much disfigured by scars after a severe burn, is said to have been unable to extend his elbows in consequence of cicatrices upon the fore-part of the arm and forearm, till one day falling down he made a forcible attempt to put out his arms for the purpose of saving himself and stretched the cicatrices; from that time he has been able to extend the elbows very well.

This contractile property of lymph is most strongly marked when its effusion is the result of active inflammation in a strong and healthy person,—that is to say, when the independent force of organization of the fibrin is greatest, and when, owing to its resistance to the assimilative influence of surrounding parts its own peculiar qualities are most fully shown. It is least perceptible in weak and cachectic persons, the fibrin of whose blood when drawn from the body sets quickly into a loose, soft, large coagulum. You have probably remarked the abundant flabby granulations and the rapid cicatrization which sometimes takes place in the ulcers of these delicate subjects, and you may have remarked too, that these cicatrices so quickly formed are thin and imperfect, contract but little, and give way again to ulceration upon very slight exciting causes.

Once organized, these false membranes,—as the deposits of lymph are sometimes called,—become constituent parts of the body, subject to the same laws of nutrition with it, and to the same deviations of those laws, or in other words to the same diseases. They may increase or diminish in size, and they may become the seat of inflammation with each of its various effects, of tubercle and of cancer. In one important respect they differ from all the natural textures, in that they do not attain to the same degree or vital force or to the same perfection of physical organization, and in consequence of this inferiority they give way before some of the common causes of disease which the other tissues are able to resist. They are the first to suffer in scurvy and other diseases of the same kind, and when attacked by inflammation they quickly fall into ulceration and mortification, and the healing processes are with difficulty and imperfectly established in them. Hence the well-known liability of cicatrices to ulcerate and the troublesome sores occasioned thereby.

Of these new productions some are the result of the reparative processes, when they take the place of a natural structure, which had been destroyed, and perform a useful office in the economy; others are extraneous or additional parts forced into existence by disease, and are altogether useless. These latter, as the common result of want of function, and in obedience to that economical law of nature, which does not suffer useless parts to be maintained at any great expense to the rest of the system, are for the most part imperfectly nourished and in course of time shrink up; or they may undergo another change which I shall again bring under your notice as an occasional consequence of atrophy—viz., calcareous degeneration, or a conversion into earthy masses, by the deposit into their substance of carbonate and phosphate of lime. Perhaps

the change may be more properly described as a transformation of the new substance into those salts. This is not ossification, for the saline particles do not appear to be arranged in any definite order, but merely to be heaped irregularly together into an amorphous mass. The calcareous masses occasionally found between the layers of adherent pleuræ are instances of this degeneration of portions of lymph which had been effused into the pleural cavity during inflammation.

Sometimes, however, it happens that the new formation instead of being subject to either of the above results of atrophy, undergoes certain other changes which bring it into a more or less close resemblance to the structures in or near which it lies. Under ordinary circumstances, lymph becomes in course of time converted into interlacing fibres which resemble those of areolar tissue, and this is more particularly the case when it is effused into that tissue or on the surface of a serous membrane. When it is placed among the tendinous structures it may assume a fibrous sinewy character, and in the neighbourhood of bones and joints it may be converted into cartilaginous or osseous substance.

The effusions into bursæ, which are the seat of chronic inflammation, and into joints, afford some curious illustrations of these changes. Here are a number of little oval bodies of about the size and shape of melon seeds, lying in the bursa beneath the annular ligament in front of the wrist; and similar bodies are not unfrequently found in that situation. They are very tough, composed of structure-like fibro-cartilage, smooth on the surface, mostly loose, but in a few instances attached by narrow pedicles to the inside of the bursa. They are probably formed of lymph effused during inflammation, and moulded into this peculiar shape by the friction to which it is continually subjected during the movements of the tendons, at the same time that it is gradually transformed into a tough fibro-cartilaginous structure in obedience to the assimilative influence of the adjacent tissues. Many, perhaps all of them, are at first attached to the lining membrane of the bursa, but they gradually become pediculated, and at last are rubbed off and float about loose in its cavity. The same explanation is probably to be given of the formation of loose cartilages in joints. There seems every reason for supposing that they originate in small masses of lymph, effused like the white patches on the pericardium during some imperceptible inflammation of the part, and that they are at first attached to the interior of the synovial membrane. They increase in size, undergo cartilaginous transformation, project into the synovial cavity, become pediculated, and at last, during the movements of the joint, are rubbed off from the surface on which they grew; then, being loose in the cavity of the joint, they are occasionally caught between the articular surfaces, and give rise to the sudden and severe pain characteristic of the disease.

These specimens illustrate some of the various forms imparted to lymph thrown out upon surfaces which are subject to attrition. On the pericardium it acquires an uneven, or more or less distinctly reticulated appearance. In these diseased and thickened bursæ it has

been transformed into tough fibrous bands and cords, crossing from one part of the lining membrane to another; and in this joint it has been converted into short fibres, set close together perpendicular to the surface, like velvet. The surfaces of serous membranes which have been for some time separated by the effusion of serum into their cavities, are sometimes sprinkled over with small, firm, glistening bodies, of about the size of millet seeds; they look like tubercles, and are sometimes described as such, but they appear to result from the coagulation of the lymph as it exudes in drops upon the interior of the membrane.

Some of these lymph formations take place without the signs of any inflammation attending them, and correspond with those insidious collections of serum of which I adduced hydrocele as an example. Of this kind, are the adhesions so often found uniting the opposed surfaces of the pleuræ in persons who are not known to have suffered any symptoms of pleurisy during life, also the white patches very commonly found in the pericardium covering the anterior surface of the heart; and nearly allied to them, appear to be those tough, dense, opaque white masses occasionally observed on the peritoneum covering the spleen and liver. These formations are interesting in a pathological point of view only, for we obtain no knowledge of their existence during the life of the patient, and they do not generally interfere with the function of the organ upon which they occur.

Fibrinous exudations may result in like manner with serous effusions from mechanical impediments to the circulation of the blood. A large loose coagulum of fibrin often forms in the serum removed by tapping from the abdomen in ascites, and the coagulation of the fibrin thus effused, together with the serum, may take place in the living body, forming the loose soft masses which are frequently found in the dropsical belly, floating about, or attached to some of the viscera.

After the enumeration of this long catalogue of evils consequent on the effusion of lymph into the cavities, and among the tissues of the body, you will feel the importance of endeavouring to arrest at an early period the inflammations of those parts in which we know by experience that it is likely to take place. I have already mentioned the beneficial influence of mercury in these cases. In iritis, for instance, the administration of mercury should be commenced as soon as the earliest symptoms of the disease are observed, and it can then be continued according to circumstances. It is one of the most effectual means of arresting such inflammations, and preventing the effusion of lymph, and it unquestionably exerts also some influence in promoting the removal of lymph already effused. The good effects of the medicine in checking the inflammation, and promoting the absorption of the lymph, are generally observable before the evidences which we are accustomed to watch for of its influence upon the system, such as a swollen state of the gums, salivation, &c., are manifested. An improvement in the condition of the eye in iritis, and a softening of the induration about a syphilitic ulcer, usually

precede the soreness of the gums and the increased flow of saliva, so that with few exceptions we may regard the first signs of mercurial influence upon the system as an evidence that the medicine is working with sufficient activity to produce its effect upon the disease. Except in a few acute cases, the advantage gained by administering mercury in such doses as to produce more than a slight soreness of the gums, is not an equivalent for the injury sustained by the constitution. In a chronic case, where the mercurial influence is required for a considerable period, a slight soreness of the gums, scarcely sufficient to attract the patient's attention, may, in most instances, be kept up with very little detriment to the health; but if, in our anxiety to hasten the cure, we go beyond this point, the increased effect of the medicine upon the disease is not proportionate to the injury done to the health, and we are often obliged to discontinue its use for a period, or altogether. I am convinced that the injurious consequences of a mercurial course may be, in a very great measure, avoided, and its good effects obtained by carefully watching the patient, so as to prevent diarrhœa, and keep the impression upon the system within the bounds which I have mentioned.

In some situations we have the opportunity of employing other more direct means, which are found to have some influence in promoting the absorption of effused lymph, such as the local application of stimulants. The application of weak solutions of sulphate of zinc, nitrate of silver, &c., facilitates the removal of a nebulous opacity of the cornea, and a blister on the skin will sometimes lead to the absorption of lymph from the indurated cellular tissue beneath. The employment of uniform moderate pressure is also alike serviceable in reducing inflammation, and in promoting the removal of solid effusions resulting from it. You will be surprised at the rapidity with which the indurated swelling of the epididymis, remaining after inflammation, may be reduced, by well-applied pressure with adhesive plaster; and the induration of the skin, and subcutaneous cellular tissue around a chronic ulcer of the leg is most quickly and effectually removed in this way.

It is not easy to form an opinion in each particular case, as to the probability of a deposit of lymph undergoing absorption, in consequence of the employment of those measures which we know to be beneficial in some instances; we are often uncertain respecting the advantage to be expected from the administration of mercury, when a recent attack of inflammation has left the pupil irregular, and the iris adherent, or from the application of stimulants, when an opacity of the cornea has existed for a month or two. I suppose that after the lymph has become fairly organized and supplied with vessels, so as to become a constituent part of the body, no impression is likely to be made upon it by stimulants or mercury, unless they be employed with severity, which would act injuriously upon the other tissues. The operation of pressure no doubt extends over a longer range of time, for if the natural tissues are not proof against its destructive effects, when they are subjected to it for a considerable

period, as in the case of an aneurism, which makes its way to the surface in consequence of the absorption of the surrounding parts occasioned by its pressure, much less can these new and morbid products resist its influence.

With reference to the last remark, it may be well to mention that the effects of each of the above modes of treatment in promoting the absorption of lymph formations, depends upon the low vitality of the new products, and their inability to withstand certain disturbing influences, which fail to effect the original or natural tissues. The mercury, the stimulants, and the pressure, are in each case necessarily applied to the new and old structures alike; the solution of sulphate of zinc produces its immediate effect upon the other parts of the eye, as well as upon the opacity of the cornea, and the bandage compresses the healthy no less than the morbid components of the limb, but the new formation yields and undergoes absorption under conditions which the healthy or natural parts are able to bear. For the same reason the influence of mercury, taken by the mouth, is generally manifest upon the disease before its peculiar effects upon the system are observed.

When lymph is effused into the substance, or upon the surface of an internal organ, we have no means at our command whereby we can in any way prevent or remove the injurious effects of its disposition to contract; but when it is situated within reach of mechanical appliances, we can sometimes interfere to prevent the contraction, or to stretch the new product after its contraction has taken place. A cicatrix at the bend of the elbow may be kept extended till it has lost the disposition to contract, and I have related to you an instance in which there is every reason to suppose that the cicatrix was stretched, after it had ceased to contract. It rarely happens, however, that we are able by mechanical means to obviate this disposition of cicatrices, which, though on the whole a happy provision, is occasionally productive of very disastrous results.

It is in the treatment of strictures, caused by contraction of lymph effused into the substance of mucous membranes and the submucous tissues, that our mechanical appliances are attended with the greatest benefit, and they operate, for the most part, in a curative rather than a preventive, manner. The usual treatment of stricture consists in the dilatation of the narrowed channel by means of bougies, which have the effect of stretching the contracted false membrane causing the stricture, at the same time that by the pressure they exert, they promote its absorption, and by the slight stimulus they impart, facilitate that absorption. The passage of the instrument is repeated from time to time, a larger size being introduced as often as admissible, till the new product has been absorbed or stretched to a sufficient extent, and has lost the disposition to contract again. In order to ensure the permanence of the cure, it is well occasionally to introduce as large an instrument as the canal will admit, for a considerable time after the full dilatation of the stricture.

The treatment of strictures consists, therefore, in

exerting slight pressure and gradual extension for a lengthened period, and you can easily understand how injurious rough and unskilful management of the disease is likely to prove. If too great force be employed, the lining membrane of the canal may be lacerated or inflammation induced, leading to cicatrization or the further effusion of lymph, and the consequent more complete narrowing of the tube. The patient pains-taking gentle surgeon is in the long run most successful in the treatment of these cases. If the instrument selected, which on first trial should be of such size as nearly to fill the canal, does not pass readily, try a smaller one, endeavour to press it on gradually and gently, expending time rather than force upon it. If it passes, allow it to remain for a quarter of an hour, more or less, and repeat the operation in a few days with the same instrument or with one of a size larger. If you do not succeed by gentle pressure continued for a few minutes in dilating the stricture so as to allow the instrument to pass, it is well to allow the patient to keep the instrument pressed against the stricture for an hour or so, and after this proceeding has been repeated a few times, the difficulty is generally overcome and the instrument passes on. I find the plan of pressing upon the stricture with a moderate sized bougie to answer better on the whole, than the attempts to pass it with small instruments, which are likely to injure the membrane and become entangled in its folds. Patience, perseverance and gentleness, are the great requisites to ensure success, and you will find few strictures which do not yield to them. In a few instances, where the stricture is of long continuance, and has been reduced to a mere thread-like constriction of the tube, its laceration by the forcible introduction of an instrument may be followed by permanent cure, but these cases are not common, and we cannot very well be apprized of the existence of such a condition.

The division of strictures by the knife is less likely to be attended with permanent benefit than their dilatation with bougies, because the wound soon heals and the contracted condition of the tube returns as bad as before.

Excision presents the only means with which I am acquainted for getting rid of the melon seed-like bodies in bursæ, and of loose cartilages in joints; the latter may sometimes be kept fixed by bandage in one part of the joint, till they acquire adhesions to the synovial membrane, and cease to occasion trouble. I know one case in which this fortunate result appeared to take place; the supposed foreign body was by a circular bandage retained in the synovial *cul de sac* above the patella, and gave rise to no annoyance during the two years in which I was acquainted with the patient after the bandage was discontinued.

OBSERVATIONS ON SCURVY

AS IT WAS DEVELOPED

IN BATH AND ITS NEIGHBOURHOOD, IN
THE SPRING OF 1847.

By JOHN BARRETT, Esq., F.R.C.S.

(Read at the Quarterly Meeting of the Bath and Bristol Branch of the Provincial Medical and Surgical Association, December 21, 1848.)

In the autumn of 1847, I promised Mr. Farr,—to whom both the public and the profession are much indebted for his valuable share in the “Registrar-General’s Annual Reports”—that I would endeavour to obtain some information on the appearance of the land scurvy in this city and neighbourhood; and with this view I sent a number of questions to various medical men whom I thought likely to assist me in the inquiry, and I have to acknowledge the courtesy and readiness with which they have given me their replies.

The land scurvy made its appearance in Bath and its neighbourhood about the middle of May, and had disappeared, I believe, by about the end of July,—that is, I do not learn that any new cases occurred after this date, though the old ones were several of them still unrecovered. I do not mean to say that none of those cases occurred before May, presenting symptoms which, strictly speaking, constitute the first stage of land scurvy, and to which I shall presently advert, but up to this period those symptoms universally recognized as land scurvy had not arisen. Thus Mr. Gore, in his weekly report to the Board of Guardians, of the state of health in the Union House says, May 29th:—“From some symptoms I have observed among the boys, I am impressed with the belief that they are beginning to suffer from the want of fresh vegetable food—ill supplied by the use of rice. Fresh lemons ordered for four of them who show signs of scurvy.” But on June 6th he reports “six cases of land scurvy, one at least dangerous; independently of these, other inmates of the ward show more or less tendency to the same conditions.”

One of my questions was—“Did you meet with cases in which, though there may not have been the swollen, red and bleeding gums, there was an anæmic state, attended with muscular or lumbar pains, waxy pallor, tendency to swelling of joints, weak pulse, languid respiration, tendency to fainting, and these symptoms unaccounted for by any particular loss of appetite or drain on the system?” Another question was—“Did you find that the diseases of the lower orders were, generally speaking, of an anæmic type?” And from the answers given to these questions I am led to conclude, that though the more marked symptoms of spongy bleeding gums, ecchymoses in the course of the tendons, &c., were not observed till May, there had been during the

spring, (to use the words of Dr. Shapter, in his interesting communication to the *Provincial Journal* at this period,) “indications of departure from the normal and healthy state of the blood, differing only in degree from that more marked deterioration in this fluid characteristic of the confirmed disease.” I call your attention to the date of its marked appearance, because, according to Huxham and Lind, in their day, the latter part of the winter and the beginning of the spring was the time of its appearance. Probably the reason that it was observed in Bath at a later period of the year than that mentioned by writers of the last century, is to be found in the difference of the food. Undoubtedly the potato in our day is used to an extent it never was before. Formerly, therefore, when from the winter, people had been deprived of fresh vegetables for some months, they began to experience scurvy at the end of that season; but in our day, the potato being used during the winter, takes the place of fresh vegetables, and when towards the spring, from the insufficient supply, the price puts it out of the reach of the poor, then between the period which elapses before fresh vegetables come in, that state of constitution arises, which terminates in direct scurvy under other circumstances favourable to its development. The cases I observed myself occurred about the end of May, and their history made good these observations.

To ascertain with any degree of exactitude the extent to which land scurvy prevailed, it would be necessary to determine the number of those cases already referred to indicating the same diathesis, but in a lower degree. I need hardly remark that this would be impossible, but from all I can learn from conversational or written inquiry, this diathesis did obtain to a very great extent in this neighbourhood in the early part of the year 1847. My brother, Mr. C. Barrett, surgeon to the Tisbury Union, informs me that about this time, a few cases of acute inflammation, when actively depleted speedily changed to the typhoid state, and a few days before death there were several blebs on the skin—those of pemphigus, except that their contents were a dark bloody serum. He had no severe cases of land scurvy, but there were many patients who suffered from the early symptoms. He remarks that there was a more than usual prevalence of purpura hæmorrhagica; and the same remark is made by Mr. Shorland, surgeon in the Westbury Union, who did not recognize any cases of land scurvy in that neighbourhood. Mr. Cockey, surgeon in the Frome Union, had two cases of land scurvy, and a friend of his met with several cases of purpura hæmorrhagica. In the Keynsham Union, Mr. Hutchins observed several cases of land scurvy, but not of purpura hæmorrhagica; none of the scurvy cases were fatal. In the Camely Union several cases of land scurvy were observed by Mr. Perrin, two of

which proved fatal. In the Bradford Union House, Mr. Highmore had sixteen or twenty cases; none were fatal.

I think it is questionable whether what is called purpura hæmorrhagica by these gentlemen, was not in reality land scurvy. It is not to be denied, that to most of us land scurvy was a new disease, and I consider the profession much beholden to Dr. Shapter for calling attention to it at the early period that he did. That some cases were returned as purpura hæmorrhagica, which were land scurvy, I can state with certainty, and I am free to confess that I did not immediately recognize its true character in the cases which came under my care. Whether there be any, or what is the essential difference, between purpura hæmorrhagica and land scurvy, I shall presently consider. I have taken some trouble to ascertain the number of cases of recognized land scurvy which occurred in Bath and that part of its neighbourhood comprised in the Bath Union. The population is upwards of 70,000, of which about 10,000 are agricultural. In the reports of the surgeons of the Bath Union, sixty cases are reported in the workhouse, and only two out of the house amongst the paupers; of these only two were fatal. At the Bath United Hospital no cases occurred;* at the Bath General Hospital three, one of which proved fatal. At the other medical charities as far as I can judge, there may have been twenty-five cases, and I think that if I say about 120 recognized cases of land scurvy occurred in the district comprised by the Bath Union, I am about the mark. This would take in the cases met with in private practice.

When I commenced this enquiry I expected to find proofs of a prevalence of diseases of hæmorrhagic character. Such has not, however, been the case. Only two cases of purpura hæmorrhagica, and fifteen of other diseases of hæmorrhagic character, such as epistaxis, hæmatemesis, &c., including apoplexy, are to be found reported as occurring at the Union House, during 1847, the average number of inmates being 750. The number reported as occurring in the different districts of the Union during the same period, is two cases of purpura hæmorrhagica, and twenty-one of hæmorrhagic character, whilst the number of medical cases in the first quarter of 1847, out of the house, was 663.

At the Bath United Hospital, out of 14,918 cases, only one was a case of purpura hæmorrhagica, and forty-one what I have called hæmorrhagic. At the Western Dispensary, out of 958, only three were hæmorrhagic; and there was no case of purpura hæmorrhagica.

* In the conversation which followed, Dr. Davies stated that he had, as Physician to the Bath United Hospital, two cases which got well under the use of lemon juice. My information was derived from the books of the Hospital, in which no cases are entered.

I think I am therefore justified in saying, that during 1847 there was rather an absence than a tendency to hæmorrhagic disease. What then is the nature of land scurvy? Dr. Budd, in his article "Scurvy," in the "Medical Library," says, p. 93, of scurvy and purpura, that they are "essentially different; they arise from different causes, they differ in the circumstances and mode of attack, and they require different treatment. We have already stated that the essential cause of scurvy is prolonged abstinence from vegetable juices, and that the approach of the scorbutic habit is very gradual; purpura, on the contrary, often appears suddenly, and in many cases it cannot be attributed to any peculiarity in diet. Scurvy, when occurring on land, is, from circumstances we have before mentioned, met with almost exclusively at the end of winter, or in the early part of spring; purpura, on the other hand, is most common in summer and autumn. The livid and spongy state of the gums, which is pathognomonic of scurvy, and which, as well as the sallow and dusky hue, is a constant symptom of that disease, is not observed in purpura. Lastly, in scurvy, bleeding always does harm, and the disease is speedily cured by the use of succulent vegetables and fruits; while in purpura the abstraction of blood is often followed by relief, and the antiscorbutic juices are rarely, if ever, productive of much benefit."

I think that part of this diagnosis, resting on the character of treatment, is open to exception, but to this I shall have occasion to recur. On all hands it seems to be allowed, that land scurvy consists proximately in an altered state of the blood, which disordered state, says Dr. Shapter, "it would appear, from the investigations of Mr. Busk, mainly consists in the amount of fibrin, albumen, and salts and water, exceeding the proportion of health, while that of the hæmatosine falls below it." (*Prov. Journal*, 1847. p. 285.) That this is attended with, or followed very rapidly by, great debility, a general failing of the vital powers, and disorganization of the textures, must be allowed by all who have either witnessed cases of land scurvy, or read the accounts of it by others. Dr. Shapter says the disease "primarily consists in a peculiar state of anæmia," and I think this would express the view taken of it by Dr. Budd, in his interesting article on "Scurvy," in the "Library of Medicine;" but if we are to take anæmia in that sense in which it is generally understood by the profession, I think it is open to exception as a description of this disease. Thus we should say of a chlorotic girl that she was anæmic, and we should very few of us think of bleeding her. But I do not think that the facts and cases recorded bear us out in considering the anæmia of land scurvy parallel with this, though I think that Drs. Shapter and Budd consider it is.

Dr. Murray, in his interesting reports on the land scurvy when it appeared among our troops at the Cape

of Good Hope, in the year 1839, (*Med. Gaz.*, Vol. xx., p. 234,) says, "I have lately had an opportunity of seeing a good many cases of it in the civil and military hospitals here, and from what I have observed I think that physicians, divested of prejudice, who carefully study its pathology in *the book of nature*, will discover an intimate connection between it and disorders of the dyspeptic and melænic classes; and that by treating it as a primary sub-inflammatory or congestive affection of the chylipoietic organs, and rectifying gastric and hepatic derangement, direct improvement in the state of the blood (which is universally allowed to be vitiated in scorbutus,) will be the consequence, and various ameliorations in the nervous and vascular actions will speedily follow (if they do not even antecede,) this salutary change in the blood;" and his view of the nature of land scurvy appears to have been derived from, at any rate is borne out by, the success of treatment in accordance with it, as I shall presently notice.

Dr. Watson, in his last lecture on the "Principles and Practice of Physic," (*Med. Gaz.*, Vol. xxx., p. 958,) adopts the view of Dr. Budd, as to the essential difference of purpura and land scurvy. "I formerly regarded," he says, "the two affections as being identical, or as mere varieties of the same disorder; but it is not so." And he then refers to Dr. Budd's article. But it appears to me that his own successful practice might have shown him that the distinctions laid down by Dr. Budd between the two diseases, are hardly founded on reality. He mentions a case occurring under his care at the Middlesex Hospital, in the summer of 1830, where such cases were, it would appear, at that time exceedingly prevalent.

"The patient, a blacksmith, 35 years old, was covered with round purple spots, of various sizes, and with irregular blotches of ecchymosis. He had vomited blood on the preceding day. He was continually coughing up blood at the time of his admission, and his wife estimated the whole quantity that he had then lost to be more than half a pailful. The interior of his mouth and palate was pouring forth blood from a number of livid fungous tumours, formed by the extravasation of blood into the cellular tissue beneath the membrane, and the subsequent rupture of that membrane. He was passing blood by the bowels, and his urine was loaded with blood. Here were the symptoms of scurvy strongly marked. In the man's history we could trace its peculiar cause. He had long been subsisting on very poor and insufficient nutriment, seldom eating any meat, but living almost entirely on tea and coffee, and bread-and-butter. He had been too ill and weak to work regularly, yet he had been obliged occasionally to over-exert himself to obtain a scanty supply of food for himself, his wife, and a large family of children. He had been a settled dram-drinker, but for some time had taken much less of that stimulus, merely because he had not the means of procuring it. His pulse was frequent and feeble." This patient was saved. "He was immediately put upon a diet of roast meat, and began to take daily half-a-pint of fresh

lemon juice, diluted with a pint-and-a-half of water, and some tonic medicine."

But Dr. Macmichael, in "Some Observations upon Land Scurvy," read before the College of Physicians April 25th, 1831, evidently referring to this case, says, "Dr. Watson's patient also was bled. And a boy admitted for scurvy under the care of Dr. Hawkins was bled, and used calomel and opium: here, too, the disease was cured." (*Med. Gaz.*, Vol. viii., p. 185.) Both he and Dr. Watson (in his lectures,) refer to a case of Dr. Latham's, at St. Bartholomew's Hospital, termed "*Purpura Hæmorrhagica*":—

"February 12th, 1828. John Davies, aged 37, a linen-draper's shopman: every part of the body sprinkled over with purpurous spots, from the size of a flea-bite to that of a silver sixpence, and all of a livid colour; in the largest spots the livid colour is deepest at the centre, and fades towards the circumference. There are, besides, several darker patches upon the extremities, of a dusky hue, as if from a bruise. The gums livid and spongy, and blood oozing from their margins in contact with the teeth. The whole tongue livid, and one half presenting the appearance of a large, black, bleeding fungus, shooting from its surface, and the other half the same appearance in circumscribed spots. On the inner surface of each cheek several black fungoid patches. The soft palate clotted with black spots. Countenance sallow; conjunctiva rather tinged with bile, and having a small ecchymosis at the inner angle of each eye." To these symptoms were added vomiting and purging of blood. "He feels a consciousness of strength, and a great appetite for food, greater than in health. There is a fetid smell about him. Pulse 120, rather small but hard. Much general anxiety." (*Med. Gaz.*, Vol. i., p. 544.)

The treatment consisted of bleeding to fifteen ounces, and two grains of calomel at a dose, and afterwards of seven grains of Hydrargyrum cum Creta, in doses of two grains and a half every six hours. He rapidly improved from this treatment.

Now, where is the essential difference in these cases: both present very much the same features, and are relieved, at least one of them, undeniably and in a marked manner, by the very remedies, one of which (bleeding,) it is stated always does harm in scurvy, whilst "mercury," we are subsequently told by Dr. Budd, "in every form should be religiously avoided?" ("Libr. of Med.," p. 94.) I do not say there are no points of difference between the cases, for in Dr. Watson's case the affection came on gradually in a state of want, and in Dr. Latham's it appears to have occurred somewhat suddenly, and there is no mention of destitution. In both there seems to have been the bleeding gums, and that bloody kind of tumour which has had the name of bullock's liver given to it, and which I shall presently mention as having occurred in this neighbourhood. The terms hot and cold scurvy given to this complaint, show that it is not always of a passive character.

Dr. Budd says, (p. 81,) "We have more than once observed, in sailors admitted into the *Dreadnought*, on account of scurvy, an extensive bruise mark on the knee or ankle, to which a blister had been applied some time previously, under the idea that the pains which the patient suffered in the limb, and which in reality were scorbutic, were owing to inflammation affecting these joints. In such cases the blister rises well, discharges serum as usual, and heals readily; but in the course of some days the patient finds the part tender to the touch, and by observing that it is the seat of an extensive deep violet-coloured spot, first discovers the real nature of his complaint." But sometimes this inflammation is not imaginary. In two cases I attended at the same time, swelling of the knee-joint occurred; in one, a man, both knees were swollen and weak, rather than painful; in the other, a woman, the left knee was swollen and painful, in short, presenting all the usual characters of synovial inflammation, and as such came under my care. It was only from the dark stains in the course of the hamstrings that I suspected the true nature of the case, and on examining the gums, and questioning her as to her food, &c., I found the appearances and history of a well-marked case of land scurvy; still I treated this local affection as synovial inflammation, and relieved it, for I should remark that she was under my treatment some days before I observed the appearance of the hamstrings, when I put her on citric acid, which, whilst I continued my attendance, was employed with advantage. But Dr. Budd himself remarks, that these extravasations are not altogether of a passive character. He says,—*"The fluid poured out is not pure blood, which always remains soft, and in some measure liquid; nor serum, which causes œdema; but a fluid which glues the parts together, and gives a feeling of hardness."* And he says of hot scurvy,—*"In such cases when blood is taken from the arm, the clot contracts firmly, and has a buffy coat;"* but, he adds, *"it is to an inflammatory action, connected with the presence of these effusions, that we are inclined to attribute the fever in such cases."* For the case of inflamed knee I have mentioned, the extravasations in the course of the hamstrings were neither sufficient nor likely to produce synovial inflammation of the knee, and consequently, I look on such inflammation as a symptom of the disease,—as a more aggravated form of that affection of the joints common in these cases, and from its active character, indicating that the original disease is sometimes active. And when we remember the close similarity of the symptoms in the cases of land scurvy and purpura I have mentioned, as treated by Drs. Watson and Latham,—that in both these cases blood-letting, and in one of them also, mercury, was employed with advantage,—that in other cases occurring at the Middlesex Hospital at the same time as Dr. Watson's, these depletory

remedies were also successfully employed, we shall, I think, conclude that there is not so evidently an essential difference between the two diseases, at any rate, that we cannot found this difference on a treatment peculiar to each, but that at least sometimes land scurvy greatly resembles purpura, not only in particular symptoms, but also in that both are remediable by treatment of the depletive character, the value of which, in purpura, I would remind you, was first pointed out by a Bath physician, and consequently, that both occasionally partake in the same, that is, sthenic, diathesis.

This question of the nature of the disease is no mere theoretical one, and that must be my excuse for dwelling so long upon it. Good common sense is, I believe, so distinctive a feature of medical men, that there are few of them who would long allow theory to contradict the plain indications of disease; still misconceived notions will naturally have their weight, and in a disease which is not of every day occurrence, it is doubly necessary that our preconceptions of its nature be correct. What then is the indication of treatment in land scurvy? If it be originally an asthenic disease, we shall use sthenic treatment, but if its asthenic character be not primary, but rather the result of original derangement, then there may be a stage, and there may be cases presented to us, in which depletive treatment is necessary. Nothing can be more distant than the views taken on this very practical question. On the one hand Dr. Budd says, (*"Library of Medicine, p. 94,"*) *"Bleeding should never be had recourse to, although acute pains, heat of skin, quickness of pulse, and other febrile symptoms of a dangerous hæmorrhage may seem to render it advisable. In advanced stages of the disease patients do not survive it; blisters are apt to produce gangrene, and for this reason we should abstain from their employment. Mercury, in every form, should be religiously avoided; even in very small quantities it has been known to produce dangerous salivation. We have met with instances in which scorbutic symptoms seemed to have been much aggravated by mercury taken before the scurvy made its appearance. The ill effects of this medicine are indeed noticed by most writers on scurvy; and Kramer, who was physician to the imperial armies in Hungary, from 1720 to 1730, relates that of 400 men affected with genuine scurvy, to whom, on the advice of Boerhaave, mercury was given, so as to induce salivation, not one survived."* Nothing can be stronger than the words of this old author;—*"Beware of bleeding: shun mercury as poison."* But when we turn to the army reports, furnished by Dr. Murray, we find just as strong a recommendation of the antiphlogistic treatment. Thus Mr. Samuel Bailey, surgeon, R. N., says,—*"I shall briefly state, that since the beginning of this year, I have made a fair comparative trial of the tonic and antiphlogistic modes of*

treatment, in sea scurvy, and that the superiority of the latter has been very marked. To a certain number of the cases I allowed a full ration of fresh meat, with soup, tea, bread, vegetables, fruit, (*i. e.*, grapes and lemons,) and beer, and gave them occasional doses of aperient medicine and quinine; and to another certain number labouring under similar symptoms, I ordered low diet, without any animal food, but with the same allowance of vegetables and fruit, and treated them medicinally by small bleedings, (where the breathing was oppressed,) mercurial alteratives, antimonials, and a full purgative dose of Epsom salts every morning. The result was, that in the former the oppression of bleeding did not subside; the appetite in the majority failed; their strength and activity improved very slowly; indeed, in two individuals, rather diminished; their skin kept dry and rough; their gums continued spongy; the lividity, weakness, and rigidity of the limbs, made scarcely any progress towards recovery; their despondency and unhealthiness of complexion continued; their sleep was unrefreshing; in short, their convalescence was protracted, and very imperfect, whilst those under the antiphlogistic plan (who, by the by, grumbled sadly at first at their getting low diet, as the others had full,) recovered in a very rapid and satisfactory manner. Their appetite and strength improved daily; their breathing became free; their countenance clear and lively; their pulse, urine, and alvine secretions, natural; and I may say, most of them were fit to be discharged to their duty before those on the tonic plan were able to leave their beds. These patients were carefully watched by some of my medical friends, known for their independence of thought and talent for observation, who all perfectly agreed with me as to the superiority of the antiphlogistic treatment."—*Medical Gazette*, vol. xx., p. 235.

The same plan of treatment, with occasionally mild mercurial treatment, with the same happy results, was adopted by other medical officers at the Cape, and the detail of the symptoms would leave no doubt on the mind that the disease they were treating was the same as that in which bleeding and mercury have been so strongly condemned. One of my correspondents, Mr. Perrin, of Camely, surgeon to the Union House, met with several cases of land scurvy in the workhouse and district, attended with spongy bleeding gums, and in the advanced stage, sloughing of the cheeks to a frightful extent. At first he treated it too much as a disease of debility, and ordered tonics, with lemon juice, and potatoes, but with little success. Afterwards he used rhubarb, and Hydrargyrum cum Creta, pretty frequently, with now and then a brisk purge, and good strong lotions of alum water, and found himself much more master of the complaint than under the first plan of treatment, and without the potato or lemon. Two cases were fatal, and he considers that he put these on the stimulant and tonic plan too soon,

though in all cases, of course after due attention to the bowels, he made their living generous, for he remarks, that the diseases of the last year were all decidedly of an anæmic character, and very few stood steady depletion for any length of time.

There is certainly no small difficulty in reconciling these different views of treatment; I would, however, suggest, whether the cases coming under Dr. Budd, at the *Dreadnought*, and which were principally seamen from merchant vessels, are not likely to have been in a more advanced stage of the disease, and consequently, with the powers of life more broken down, than the patients of medical officers at the Cape, or than my correspondent, Mr. Perrin's patients. They probably had, for some time before treatment was commenced, been suffering from it, and the stage in which depletion is right may have passed, and have left a state in which it could not be borne. We know how much the question has been mooted, whether bleeding is right in cholera. From cases which came under my observation, whilst a pupil in town, I was satisfied that there was at least sometimes a stage in which it might be used with advantage, but this rapidly passed off. I do not mean to say that in land scurvy this stage passes off with anything like the same rapidity, but merely that cases of decidedly the same disease may have been differently treated with success, from their being met with in different stages; and I am the more induced to take this view of the difference of opinion by observing, that one of the medical officers at the Cape, who seems to favour the tonic plan, was surgeon to the hospital where the patients affected with land scurvy were received from the outposts; they were not cases originating in the hospital, and consequently had been some time affected when they came under his care. "I have no doubt," he says, "that had either bleedings, or strong saline purges, been used in the severe cases, they would have sunk; and I further think, that if a vein had been opened, it would not have united; in short, that the antiphlogistic practice would not have been advisable in any of these cases. The rapidity of recovery effected by change of air, comfortable quarters, the liberal use of port wine, and such like treatment, was surprisingly great, except in the man who was in a moribund state at the time of his admission into my hospital."—*Medical Gazette*, vol. xx., p. 942. It appears to me that this may be perfectly correct, and yet that these very cases may have previously presented symptoms indicating depletion.

The practice at the Cape, which consisted principally in bleeding and saline purges, was, in truth, antiphlogistic. Mercury does not seem to have been often used; but I have brought forward proofs that it may be used with advantage in this disease, though proscribed in the strong language I have quoted from the old author Kramer, and adopted by Dr. Budd. "Shun mercury as you would poison." Perhaps, if

Dr. Budd's objection to it be founded on practice, it may bear the same explanation I have given of his objection to bleeding,—that his cases had passed the stage when depletion could be borne; and in judging the value of an opinion on the use of mercury some hundred years ago, we must take into consideration the modes of employing it now, and then. A knowledge of what mercury can do when properly used, and what it will do when improperly used, is amongst the best proofs of our improvement in medical science—it is at once the most remedial and destructive agent we can employ, because its effects are most definite; and if Kramer saw it used in land scurvy in anything after the fashion it was used amongst us some fifty years ago, it is no very great wonder he should have reprobated it in a disease so rapidly tending to depression.

But there is one remedy which has met with nearly universal approbation—citric acid or lemon juice; it would appear to have been used by the medical officers at the Cape, in conjunction with their antiphlogistic plan; and all parties seem to consider, that whatever may be the proximate cause of the symptoms of land scurvy, and consequently the indications of treatment to be derived from diathesis, the primary cause is the want of some principle in the animal economy which an organic acid supplies, and that none is equal to the citric acid. In the cases which came under my own treatment, but which were not aggravated in their symptoms, I found the citric acid of commerce sufficient. Mr. Harries, of this city, informs me that he did also, though he continued it for a long time it would seem before it fully effected a cure. But some of my correspondents employed the fresh lemon. Mr. Gore ordered fresh lemons and green vegetables for the cases at our Union House.

Mr. Highmore, of Bradford, first treated the disease in the Bradford Union House by a total change of diet, giving fresh vegetables, and citric and mineral acids, quinine and other tonics, *without the slightest success*. He then obtained a supply of lime juice, which was given to all the children, healthy and diseased, two ounces to each daily, with sugar and water. After the first few days from adopting this plan, no fresh case occurred, and it was sufficient to cure those already ill, some of whom were in a most pitiable condition, the spongy bleeding gums overlapping the teeth, and the cheeks, in two cases, deeply ulcerated. But other acids were employed with success.

Mr. Foster, the surgeon to the Taunton Union House, informed me that he made the patients there drink rough cider, and eat plenty of fresh vegetables, and they got well. My brother, (Mr. C. Barrett,) in the Tisbury Union, employed sulphuric acid, vegetable diet, and tonics, with speedy relief. Dr. Lindoe, physician to the Walcot Dispensary, met with about a dozen cases which he recognized as land scurvy, but he states that he found more than a usual prevalence of purpura

hæmorrhagica. His treatment consisted in saline diaphoretics, with acidulated drinks, followed by vegetable tonics and diluted mineral acids. Dr. Samuel Edwards, of London, late physician to the same dispensary, writes me that he treated his cases, which were not aggravated ones, on the tonic plan, vegetable bitters, with mineral and vegetable acids, but, above all, the "Charity Ball" tickets, by which means he was able to supply good meat soup, meat, and sometimes vegetables. Mr. Hutchins, surgeon to the Keynsham Union House, where the disease appeared, informs me that medicines were not generally well borne. He used alteratives, slight purgative, tonics, with light nutritive diet and stimulants. His cases were of slight character.

(To be continued.)

CASE OF EMPYEMA,

IN WHICH NINETEEN PINTS AND A HALF OF PUS WERE REMOVED BY AN OPENING MADE INTO THE CAVITY OF THE CHEST, WITH REMARKS.

By JOHN TUCKER, Esq., Surgeon to the Exeter Dispensary.

(Read to the Devon and Exeter Pathological Society, at the Exeter Dispensary, February 2nd, 1849.)

The attention of medical practitioners having been of late frequently called to empyema and paracentesis thoracis in several of the medical publications, induces me to relate to the members of this Society a case which some time since occurred in my practice. There are many remarkable circumstances with which it is connected, so that I venture to anticipate a brief report of it will not be considered as uninteresting by the majority now assembled.

On the 30th of June, 1837, James Tucket, aged 26, of Ashton, in this county, consulted me. A few days previously he returned from the Island of Jamaica, where he had spent the last six years in the capacity of an overseer, which in the West Indies is understood as the manager of an estate. I had known him well before he left England, when he was in rude health and had never shown any predisposition to disease. The change now, however, which had taken place in his constitution, forcibly struck me, for his general appearance was that of a person in the last stage of phthisis, and so were his symptoms, for he had a most harassing cough, great emaciation, pulse 130, cedematous state of the legs, and expectorating daily from a pint to a pint and a half of purulent matter.

The history he gave me of his case was as follows:—That for more than twelve months he had been in an ailing state, suffering from boils in various parts of his body, which were relieved by occasional doses of blue pill and laxative medicine. These disappearing, slight pains were often felt in the left side just below the ribs, and which increased when he coughed or laughed.

He was advised to wear a belt tightly buckled around him, and to rub a liniment composed of camphor, hartshorn, and turpentine, with a little oil. This gave him relief so that he was able to follow his occupation on horseback. On August 3rd, 1836, was on horseback during the greater part of the day; went to bed at nine o'clock fatigued, but quite free from pain, and fell asleep. At 12 o'clock he awoke with violent pain in the left side just below the ribs, and was unable to lay in the horizontal position. So great were his sufferings, that at break of day he sent for the medical attendant of the estate. He was bled to faintness, and had given him some calomel and antimony with purgative medicine. For the time he was much relieved, but as there were frequent spasms in the side, and tenderness on pressure, a large blister was applied and kept open. Every attention was paid to diet and to the action of the bowels. On the 20th, the pain in the left hypochondriac region again returned with great uneasiness about the blade-bone and up the neck, accompanied with difficulty of breathing, evacuations quite white. Was again bled largely and a good-sized blister applied over the affected part. Several blisters were had recourse to and he took a good deal of calomel and laxative medicine. Was much relieved and remained in a convalescent state till about the beginning of April, 1837. At this time he discovered a tumour in the left side, under the ribs, which increased to the size of a foot-ball, very hard, and if pressed caused him a great difficulty of breathing. Severe rigors came on, and he was at times feverish, lost his appetite, became thinner and legs much swollen. Was advised to visit his native country, and on the 11th of May went on board ship for that purpose. On the fourth day a gale of wind sprung up, which caused considerable sea-sickness, and during the act of vomiting the tumour in the left side suddenly left him. This was followed by the greatest difficulty in breathing, almost amounting to suffocation, was unable to lay down in his hammock, and the only relief he could find was in an erect posture. In this state he remained until the 18th of May, when a very large expectoration took place on a sudden, and which gave him considerable ease, and he was able to respire more freely. At this period the cough become most harassing, in fact it never ceased, caused by the constant and great expectoration. He came on shore June 21st, and made the best of his way into Devonshire.

June 30th. His father brought him to my house, and in the state already described. I thought it right to examine the chest first by measurement, with a tape, just below each nipple. The entire was forty-one inches and a half. On the right side I found it nineteen inches; on the left, twenty-three and a half, with considerable more rotundity, and the intercostal spaces were much wider apart. Secondly, with the stethoscope. In neither region of the left side could any sound be heard, and by percussion every part was dull, but on the right the respiration was generally audible, and what Laennec has called puerile. The position of the heart was towards the right side, and in no part of the left could its pulsations be felt. There was no doubt in my mind as to the nature of the case,—viz., that a large collection of fluid

existed in the chest, and the only remedy which I held out to him was its removal by an operation. This I explained to him and his father, but at the same time advising that some other medical practitioner of eminence should see him with me in consultation. Dr. Macgowan was fixed on, who, after making every enquiry, and minutely examining the chest, came to the same conclusion as I had. Several of my medical friends subsequently saw the patient, and we all agreed. The poor fellow could not make up his mind to submit, and all that was done was to sooth and allay his symptoms with large doses of hyoscyamus, and the different preparations of opium. In this state he went on, occasionally coming to Exeter, but evidently getting weaker and more emaciated, until September 20th, when he took lodgings, having resolved to submit to anything I suggested, for his distress was such, to use his own expression, that he preferred death.

On the 30th of September I performed the operation by an incision between the seventh and eighth ribs, an inch in length, in the presence of Dr. Macgowan, and my pupils, Messrs. Macdougald and Roberts. The pleura was astonishingly thickened, and on being punctured, gave exit to five measured pints of purulent and most offensive matter. Becoming very faint, we placed him in the horizontal position, and administered a little wine. The relief he experienced was very remarkable, for his cough immediately ceased, and he was enabled to lie on his back. In the evening I visited him again, and found him very comfortable and grateful for the relief which had been afforded him. I forgot to mention that in the opening a pledget of lint was put when the faintness took place. As we were quite aware that a large quantity of matter still remained, I thought proper to place him on the left side, and remove the lint; about four pints and a half of pus was evacuated. Previous to the operation the pulse was never under 110, but after, and at this visit, I found it at about 80. The dyspnoea was now quite gone, so that he could lie on his back without distress, which he had not been able for at least twelve months.

October 1st. Has slept many hours, and had no fever. Removed the plug, when about two pints flowed from the wound.

4th. Complaints of oppression over the chest. Took away the lint, but nothing escaped.

6th. In great distress; pulse 120; and unable to lie on his back. Passed a common-sized trocar into the wound, and removed two pints and a half of the same kind of pus. He passed a tranquil night, and was again able to lay with comfort on his back.

7th. Considerable derangement of the digestive organs; vomiting and purging, of a green bilious matter; cough increased, and expectoration of a yellowish green fluid. This caused great exhaustion; however he rallied by the 11th, and left Exeter for his own home, which is about eight miles, on the 13th.

I visited him on the 16th, and found all his symptoms had returned, and the legs again becoming oedematous.

On the 18th, finding him in great distress, I advised another puncture to be made; this I did between the ninth and tenth ribs, about six inches from the spine, with a

CLINICAL ILLUSTRATIONS.

ON CORRODING ULCER OF THE UTERUS:
CASE AND REMARKS.

By EDWARD BALLARD, M.D., of Leamington,
Late Senior Physician to the St. Pancras Royal General
Dispensary, and Medical Tutor in University College,
London.

The difference of opinion which exists among medical authorities respecting the nature of that disease of the uterus which passes under the name of corroding ulcer, induces me to furnish the narrative of a case which occurred in my own practice. The publication of it was further suggested to me by the appearance, in the first number of the Journal for the present year, of a clinical lecture on the subject, by my friend Dr. Heaton. I may premise respecting the rarity of the affection, that it was the only case which occurred to me during the five years that I was attached to a large public dispensary, although numerous cases of cancer, and simple ulceration of the womb, presented themselves for treatment.

CASE.

Frequent Miscarriages; trifling Hematuria; sudden Vomiting, with Pain in Loins, &c.—Vaginal Discharge; Ulcer of Cervix Uteri; Cystitis; Vaginitis; Discharge of Urine by Vagina; Death.—Post-mortem examination:—Corroding Ulcer of Uterus; Communication between Vagina and Bladder; Cancerous Deposit, &c.; Ovarian Cyst; Ulcers, &c., of Gullet, &c.

A. G., aged 50 years, residing in a tolerably healthy part of Somers Town, but six years before had been living on the banks of the Regent's Canal, where fogs and mists were almost continual, except in very fine weather; of lymphatic temperament and cheerful disposition. No hereditary taint to be traced. She placed herself under my care, at the St. Pancras Dispensary, on May 18th, 1846. The history taken at that time was as follows:—So far as can be ascertained, her habits have been temperate. She has, during the last few years, undergone some amount of privation, but has always been adequately clothed. She has been married twenty-five years, and her husband is living. Her first child was born fourteen months after her marriage. The labour was protracted over three days and nights, but she was ultimately delivered without instruments. She then suffered one or two miscarriages, and in three years after had another child. This labour was favourable, but was followed for three months by a thick, yellow, and exhausting vaginal discharge. Since then she has had four other miscarriages, at early periods of pregnancy, not accompanied by much flooding; the last was four years ago. The catamenia commenced rather late,—namely, between eighteen and nineteen years of age; for the last eight or nine years have occurred at more prolonged periods than formerly, and although latterly clotty, have not become more abundant.

With the exception of slight catarrhal affection, her

middle-sized trocar, when five pints and three quarters of most offensive matter rapidly escaped. Now I determined on keeping in some hollow tube, and I passed about two inches of an elastic-gum through the canula, which I withdrew, leaving the former, plugged with a bit of wood. Previous to my leaving him I thought proper to substitute the canula of an hydrocele trocar, which I had prepared, with four holes at the shoulder, in order, with tape, to tie round the body: into the opening I also passed a plug, and instructed him how to use it, if any distress occurred. From day to day he did so, and at each time three or four ounces escaped.

On the 21st I again visited him; found him in excellent spirits; little cough, and was not at all distressed when laying on his back.

On the 28th I again saw him, and was surprised to see the alteration which had taken place. He was down stairs, and felt quite convinced he should recover. Appetite good; little cough; sleeps well; pulse 75; is gaining flesh; takes a good deal of raw milk; no oedema of the extremities. Removes the plug from the canula about every third day, and evacuates two or three tablespoonfuls of fluid.

On the 10th of November was enabled to ride to Exeter and back again in a spring market cart. Still continues to mend, and is looking healthy.

For several months I did not see him, but heard that he still kept the canula in his side, and was very well.

In September, 1838, was so very much recovered as to enjoy the sports of the field; he was cautioned, however, to be careful in every respect. The winter he passed well, had regained his strength, still wearing the canula, and occasionally taking out the plug.

In the spring of 1839 was so well as to return to the West Indies, since which he has married, and is the father of two children. A few months since he wrote me a grateful letter, stating his perfect restoration, that he was the manager of a large estate, and often tired three horses a day. Up to the present period he still wore a canula, and as it caused no inconvenience to him, intended to do so. Of so corrosive a nature was the secreted matter, he informed me, that besides the instrument I gave him, he has been obliged to purchase four since. In my reply to him, I advised a canula made of platina; whether he has procured one of this metal I am unable to say.

Thus favourably has this case terminated; and when all the circumstances are borne in mind, little doubt will exist but that originally a large abscess formed in the liver, which made its way through the diaphragm, and ultimately into one of the bronchi. Instances of the kind are not very rare of patients having survived; but my firm belief of this young man is, that had not the operation and subsequent practice been adopted, his life would not have been spared.

health has been, on the whole, good. Depression in her circumstances has preyed much upon her mind for the last seven years, but she continued in her usual state of health, making no complaint whatever up to the beginning of the last month, (April.) She states that on a Monday, at that time, she became wet through, and on the following Thursday walked a distance of two miles, to visit a friend. She felt very tired, and partook of some warm ale, and while returning, and near her own house, was suddenly seized with sickness and vomiting, accompanied by a dull aching pain across the loins, such as she used to experience when unwell. For some days before this attack her bowels had been irregular, and now became much confined, the stools being hard, and defæcation being accompanied by shooting pain. The house-surgeon of the Dispensary, and another medical gentleman, had seen to the freeing of the bowels about a fortnight after the attack, but up to the time of her coming under my care, the pain first complained of had been increasing. She states spontaneously that for some time the urine has been occasionally bloody, but she does not recollect whether this symptom preceded the occurrence of pain. For the last two or three years she has felt rather poorly in the spring, blood occasionally passing from the anus in small quantities, but disappearing after a dose of Epsom salts. During the same period, at spring and autumn, a watery vaginal discharge, occasionally bloody, has also appeared; it never had any smell. The catamenia appeared last on the 15th, and disappeared last night. They were very abundant.

She has lost flesh considerably since her attack; the lips and cheeks are pale, and the surface generally sallow; this tint, however, having appeared only since her illness. Complains chiefly of aching pain, extending from the loins down the back of the hips, and in the inside and outside of the thighs, sometimes accompanied by pain in the groin. Sometimes the pain is of a shooting character; it occurs for an hour before and after every stool. There is slight tenderness in the situation of the pain, especially behind the hips. The veins of both legs are very extensively varicose. She complains specially of the pain across the loins, when rising from her chair, leaning back in it, or on attempting to reach anything placed high above her head. Her pains are all worse when she first goes to bed, and do not leave her all night; worse also when sitting by the fire; but better if anything, when she is walking. Micturition is not painful, nor unusually frequent, but sometimes is rather difficult.

May 20th. Yesterday began to experience a sense of fullness, heat, and swelling in the vagina; some red discharge has appeared; slightly duller under right clavicle than under left; respiration rather defective under both.

22nd. The red discharge ceased yesterday, and now says that only a clear watery discharge remains; says the vagina feels full, "as if something as large as a nut were in it," and tender.

Vaginal examination.—On introducing my finger I could only perceive the base of the cervix uteri remaining,

the rest being replaced by an ulcer, apparently somewhat larger than a shilling, directed backwards in such a manner that the finger impinged at first upon its lower and anterior edge; the edge felt hard and irregular, and was very tender; the body of the uterus was felt beyond it, being somewhat anteverted. The introduction of the *speculum* gave great pain, so that the examination by this means was rather imperfectly performed. The part of the ulcer seen was deeply red on the surface, and a copious reddish watery discharge welled up from it. The vagina was healthy.

She had been taking up to this time only some gentian and bebeerine, and I merely ordered, in addition, that the vagina should be kept washed out with warm water, and a pitch plaster to be placed on the loins.

28th. No relief; urine contains no albumen, it presents a dense cloudy deposit, containing mucous corpuscles, epithelial scales, and a very few large nucleated corpuscles, which may be cancerous.

She now began to use suppositories of opium, and injections, containing the *Liquor Opii Sedativus*, which occasionally gave some relief to her pain, but the bowels became so difficult to manage that the use of these remedies was shortly suspended.

Towards the end of June, the pain and discharge continuing, with but little variation, she began to suffer, in addition, from sensations of pricking and shooting about the abdomen. The pain of the loins extended up the back, and settled in a great measure over the sacrum; and she began to complain of a sense of "tearing open" of the perineum and vagina. Her pains were all increased by any change in the weather. A liniment of tincture of aconite appeared to relieve her a little.

On the 15th September the vaginal discharge was, for the first time, noticed to present a disagreeable odour. All her pains have been much worse since the 12th, when a small black clot came from the vagina.

22nd. Pains very severe, with sense of bearing down; has passed another clot; sense of stiffness over the abdomen.

29th. She was compelled to keep her bed, and continued to do so up to the time of her death.

October 6th. Has been vomiting daily; great weakness; œdema of feet; complaints of aching pain in the left hypochondrium, with tenderness; tenderness also in the right flank, and below the margin of the ribs on both sides, and also over the hypogastrium; there has been slight diarrhoea the last two days; the cancerous odour obvious in the vaginal discharge. On physical examination of the abdomen, the liver was perceived to be much lengthened, and some solid organ, either the spleen or left kidney, was felt below the left false ribs. The pain in the left loin was relieved by the application of a few leeches.

9th. Some leeches were applied above the crest of the left ilium, for relief of severe pain in that situation.

13th. Complains of a burning sensation in the throat when she swallows, and points as its seat to the commencement of the trachea; aching pain over the whole abdomen, with general extreme tenderness and muscular

resistance to the pressure of the hand. Turpentine fomentations to abdomen.

14th. Pains all intense; urine contains pus and exudation corpuscles, octohedra and oval plates of oxalate of lime, phosphatic prisms and blood-disks. For some days past has been lying with the legs drawn up, and has been complaining very much of the severe sense of burning in the vagina; and there is excoriation at the top of the thighs from the discharge; tongue has been very tender for the last day or two. The burning sensations of the vagina, &c., were relieved by the use of warm fomentations.

During the last few days of her life the abdominal and lumbar pains appeared obscured, by the intense burning sensation in the vagina.

19th. The urine passed from the vagina with the discharge involuntarily, although some was still retained in the bladder, for the purpose of passing which she occasionally rose; the countenance became exceedingly anxious; the vomiting was incessant; the urine presenting a black gelatinous deposit of altered blood; the abdominal tenderness would not allow of any manual examination. She died on October 23rd.

The body was examined fifteen hours after death.

Emaciation considerable; but on opening the abdomen the liver was found remarkably (not extreme,) elongated, and all the abdominal organs very much displaced. The tumour beneath the margin of the left false rib was found to be the kidney. All this appeared to be due to a habit of tight lacing which she had contracted when young. The *omentum* was very small, and attached to a round tumour on the left side of the pelvic cavity; it was extremely thin, and contained no fat. With the exception of its altered shape, and a deep transverse constriction, the *liver* was healthy. *Stomach* perpendicular in direction; much narrowed; mucous membrane of the fundus reddened, mammillated, and thickened. *Small intestines* generally contracted in diameter; the mucous membrane of the ileum of a deep bistre tinge, becoming paler as the upper part was approached. The jejunum varied from a deep pink to a moderate bistre colour. Large intestine in the greater part contracted; its mucous membrane deeply reddened; some punctiform ecchymoses in the cæcum. As it passed into the *rectum* the mucous membrane was considerably thickened and corrugated transversely, increased in consistence, and presented small dots of a red colour, evidently the openings of granular follicles abundantly scattered over it. The *right kidney* was in its natural situation, but the elongated liver completely concealed it; it was considerably smaller than the left; pelvis much distended, so that some of the calyces were obliterated, the papillæ opening into the general cavity of the pelvis, which contained about half an ounce of pretty clear urine. Its capsule stripped off readily, leaving the surface of the organ smooth, pale, and faintly mottled; section pale; thickness between the pelvis and outer surface only a quarter of an inch. Cortical and conical portions both so pale and contracted that they were scarcely distinguishable, and very dense in consistence. *Ureter* on right side measured two inches in circumference. *Left*

kidney presented the pelvis less distended, and the other appearances similar to, but less marked than the right. *Left ureter* measured one inch in circumference. The *left ovary* formed a rounded tumour measuring two inches in diameter, adherent to the wall of the pelvis opposite the great sacro-sciatic foramen; it consisted of a stout sac containing a clear reddish liquid. The interior of the sac was lined by a membrane, in parts of a deep bluish black tinge, apparently due to ecchymosis, and projecting here and there from the wall were small kidney-shaped oval or round elevations more or less deeply red in colour; and semi-cartilaginous in consistence. The *right ovary* and *Fallopian tubes* were healthy. The *bladder* was contracted, and when opened along the anterior part was found to contain no urine. So much of its inner surface as was not in juxtaposition with the uterus was entire; but opposite the upper part of the vagina and lower part of the uterus, was an ulcerated gap by which the bladder communicated with that canal, the cervix and lower and anterior part of the body of the uterus being also destroyed. To such an extent had the ulceration at the top of the vagina proceeded, that in passing up the finger very cautiously it broke through it posteriorly and entered the cavity of the peritoneum in the recto-uterine pouch. On the inner surface of the bladder the large ulcerated opening was bounded by a hard thickened border, presenting an ash-coloured surface and flocculi, ash-coloured superficial sloughs being seen upon all the adjacent portions of the mucous membrane of the bladder. The opening was three quarters of an inch across. There was a second small opening about the size of a pea, lying to the right, and anterior to it and separated from it, by a thickened cord of dense tissue about a quarter of an inch wide, in which ran the right ureter. The base of the bladder was separated from the vagina by a mass of hardened thickened tissue, measuring about an inch in transverse direction, which formed the anterior border of the ulcerated aperture. At its two ends were the openings of the two ureters, much contracted, so that a blow-pipe could not be passed more than half an inch along them. The rest of the mucous membrane of the bladder was deeply reddened, and at the right side near the ulcer, was thrown into longitudinal wrinkles. The principal part of the membrane was of natural thickness and consistence. At the opening of the *meatus urinarius*, there were longitudinal red stripes of ecchymosis, one much elevated, and presenting when cut into, a clot of blood.

The uterus was about the natural size, congested on the posterior surface. The vagina was opened up from behind in order to display the full extent of the ulceration. The ulceration was then seen to have destroyed the cervix and to have extended a certain distance up the anterior part of the body of the uterus. The upper part of the vagina and the ulcer on the anterior part of the body of the uterus had opened into the bladder, in the situation above mentioned. The whole surface of the ulcer was very irregular and covered with ash-coloured shreds, as well as with a dirty reddish-brown mucus-looking secretion. The

vagina presented deep ulceration, also with ragged borders of various sizes; some of them, however, were quite superficial; they appeared to be independent of any morbid deposit. Cavity of the uterus of natural size, and mucous lining moderately congested. Tissue for about an inch below the fundus about natural in appearance, except being stained of a rather deep reddish tint to the depth of a couple of lines from the outer surface. Below this part, however, or for about half an inch above the ulcerated surface, this tint was general, deepening very much as the ulcer was approached, and presenting here and there little ecchymoses, especially adjacent to the uterine cavity. There was a rounded elevation on the surface of the uterine ulcer, whose section presented a semi-bluish tinge in points, mixed with natural tissue. Its texture was indurated. The tissue forming the septum between the bladder and vagina presented similar appearances, both exhibiting some abnormal deposit. Portions of this tissue placed under the microscope, displayed cells similar to those of cancer,

There were trifling, rather recent, adhesions of the apices of both lungs, especially observable, however, on the right side. No considerable disease in the heart or lungs. On the anterior wall of the commencement of the gullet, opposite the cricoid cartilage, were several linear shallow abrasions, varying in size but none exceeding a quarter of an inch in length. Accompanying these were little elevations, varying from the size and shape of a pin's head to that of a caraway seed, containing a pellucid fluid, one larger than the rest was situated close to one of the excoriations. These vesicular elevations were accompanied by obscure striated redness, and extended scattered scantily over four inches of the gullet below the cricoid cartilage. Laryngeal cartilages ossified.

(To be continued.)

PROVINCIAL Medical & Surgical Journal.

WEDNESDAY, MARCH 21, 1849.

We have inserted in another column, at the earnest request of the author, a letter on Medical Reform, in which it is stated that the subject "has not made its appearance in the columns of the *Provincial Journal* in a way that might have been reasonably expected." We have great respect for the author of the letter as a sincere well-wisher to the entire profession, and a most zealous and energetic advocate of reform; but, notwithstanding that many of his opinions are in the abstract correct, we feel quite assured that, in the present state of the profession, it would be impracticable to carry them out. No mere human institution is, or can be, perfect; nor with the manifold differences of opinion,

and the endless diversity in the constitution of the minds of men, can any system be devised which shall be to all equally acceptable. Under these circumstances, in any changes which may be now adopted, each sect, we might say each individual, will have to give up some, perhaps favourite, opinion, in order to secure the acquiescence of others in those general measures in which all are manifestly interested.

For instance, no one we believe questions the value of a registration of all duly-qualified members of the profession; but the form which this registration is to receive,—whether Dr. A., Mr. B., and Mr. C., men of first-rate character and standing in the several branches of the profession, are to be respectively arranged, in alphabetical order, with Dr. A., Mr. B., and Mr. C., equally qualified in the eye of the law, but professing homœopathy, hydropathy, or some other of the fashionable quackeries of the day, or whether separate class-lists are to be adopted, are points on which various opinions are entertained, and which it would seem are not easily to be adjusted. No one we believe will deny, that it would be far better to separate the trade in medicines from the practice of the profession; but whether this is to be done by giving up the dispensing of drugs altogether, or by a limitation of the charges of the dispensing practitioner to fees for advice and attendance, or whether, indeed, it admits of any arrangement at all without cutting up the practice of the medical man altogether in rural districts, or transferring a still larger portion of it to chemists and druggists in towns and densely-inhabited places than they have already appropriated, is very questionable. The public generally, and amongst them even many medical men, are advocates of free-trade in physic. With such views we see not how the general practitioner is to hold his ground against the retailer of drugs, or at any rate retain a large portion of the practice which he at present possesses. Were the profession now to be constituted for the first time, such difficulties would still exist, though perhaps not to the same extent as at present.

We are not, however, contending for these individual points, our object is to show that such diversity of opinion exists on these and other questions connected with Medical Reform, as to render the idea of the attainment of unanimity upon the entire question, without each party or individual yielding somewhat to

the opinions of others, altogether Utopian. It was with this conviction, therefore, that we hailed with satisfaction the late conference in London, and were disposed to receive the results, on the whole, as a considerable step towards the accomplishment of a re-construction of the entire profession, on grounds as favourable, perhaps, as could be hoped for. The conference would, no doubt, have been more influential had it embraced deputations from other bodies of the profession, as was indeed originally proposed by the Council of the Provincial Association. Two large bodies in particular were left unrepresented,—the provincial physicians, (Graduates of Universities, and Licentiates *extra urbem* of the Royal College of Physicians;) and the associated surgeons, members of the College of Surgeons, but whose privileges had been violated by the provisions of the new Charter. The Council of the Provincial Association immediately on becoming acquainted with the results of the conference, requested the opinion of those gentlemen who had thus been excluded. The provincial physicians responded to the call, and through the representations of a deputation from the Council of the Association to the College of Physicians, several modifications were introduced into the clauses of their proposed new Charter, so as to render that document such as, upon the whole, it was believed might prove satisfactory to that branch of the profession. Only two declarations were received from provincial surgeons respecting the results of the conference, and these did not obviously afford, numerically, sufficient grounds upon which to send a similar deputation to the College of Surgeons.

The Council of the Provincial Association having thus succeeded in satisfactorily arranging the objections with the College of Physicians, and having failed to elicit from the surgeons any documentary evidence on which to apply to the College of Surgeons, and seeing that the members of the National Institute of Medicine, Surgery, and Midwifery, professing to represent the general practitioners, were satisfied with the results of the conference, could only infer that such results were, on the whole, if not altogether satisfactory, such as the great majority of the profession would be disposed to receive. It was unnecessary, therefore, to keep up, or further protract, a discussion in the pages of the *Provincial Journal*, of a subject grown distasteful to many, from the years which had already been

consumed in agitation, when the object seemed at last to have been attained.

Nothing can be more injurious to the best interests of the entire profession, and of its members individually, than the present distracted state of our institutions. The Government and the Legislature are weary of our dissensions. They are willing, it is professed, to legislate for us, provided we can agree amongst ourselves. If the results of the late conferences, corrected and amended by the evidence which has been brought before Mr. Wakley's committee, are not to be taken as the ground-work for general legislation, we know not where it is to be looked for. A renewed agitation at this, the eleventh hour, having any other object than an amended Charter to the College of Surgeons, by which justice may be done to its excluded members, would, we much fear, lead only to the indefinite protraction of the settlement of the question, thus leaving the profession, for years to come, disunited, powerless, and as a public body, if indeed its institutions, such as they are, fall not utterly to pieces, continually exposed to public contempt.

Reviews.

Pathology of the Human Eye. By JOHN DALRYMPLE, F.R.C.S. FASCICULUS I. Folio. Plates.

The intention of the author in bringing out this work, as we are informed in the introduction, is not "to publish a *treatise* on diseases of the eye, but rather to exhibit them as they occur in nature, in a series of drawings, with such explanations as shall identify them with symptoms, and with the general treatment of the case." Considering the number and excellence of the standard works on diseases of the eye which have appeared both in this country and on the Continent, since the commencement of the present century, Mr. Dalrymple has, we think, judged rightly in throwing the results of his experience into the present form. His work thus becomes illustrative of any one or all of these systematic treatises, and indeed makes frequent reference to many of them for details of symptoms and treatment; while, through its admirable coloured drawings, it at once brings the objective symptoms prominently forwards, and characterizes and defines them in the accompanying text in such a manner as to render the work most valuable for study and consultation.

In the present fasciculus are delineated, in four plates, each containing six coloured figures, chronic conjunctivitis, and its sequelæ; tinea ciliaris; lippitudo, ectropium, trichiasis, entropium; pterygium;

symblepharon; anchyloblepharon; hordeolum; encysted tumour of the eyelids, and other morbid growths from the tarsi and conjunctiva. Of the manner in which the drawings are executed and coloured, it is scarcely possible to speak too highly; they are beautiful and characteristic representations of the diseases which they illustrate, and the entire work, if completed in the same style of excellence, cannot fail to give the highest satisfaction to those who may become possessed of it.

Proceedings of Societies.

NORWICH PATHOLOGICAL SOCIETY.

J. G. CROSSE, Esq., F.R.S., President.

The President said that he had a duty to perform which it was painful for him to undertake, and which would, probably, cast a gloom over the future proceedings of the day. He was not about to occupy their time by a long and studied address, what he had to say would be dictated by his feelings without preparation; the subject indeed was one upon which a person, even as little accustomed as himself to address a public meeting, ought to be able to express himself with sufficient effect without premeditation—he alluded to the death of their late respected Vice-President, Mr. W. Henchman Crowfoot, whose loss would not be regretted by themselves only, but also be deeply felt in the whole district, including several of the eastern counties. Mr. Crowfoot became a member of the College of Surgeons in 1801, and was also chosen a Fellow of the same College recently, when a new grade was introduced. Meeting with inadequate success in a smaller town, he removed to Beccles, where he practised (and we know how he practised,) for nearly fifty years. He was possessed of all the qualifications necessary to successful practice; his manners were easy and fascinating, his disposition kind and obliging, his head well stored with knowledge, and his industry and zeal constant. He was esteemed by the profession and the public, but he was beloved by all who had the happiness and privilege of his intimate acquaintance. The foundation of this twofold esteem they would have no difficulty in comprehending, if they knew how much he had at heart, the respectability of his profession, and the welfare of his patients. Mr. Crowfoot was not a genius; he did not all by fits and starts; he was always careful, industrious, observant, and thus he became possessed of a great fund of information which rendered his assistance acceptable, and his opinion really valuable. His kind nature, and the modesty of his own opinion, forbade him to think ill of any of his professional brethren, and in cases where the more sturdy of the profession shewed the *odium medicum*, he forbore to come to an unfavourable decision.

Gentlemen, my tale is shortly told. Mr. Crowfoot was taken ill on the 9th of November, after being present at a *post-mortem* examination of a lady who had died of low fever; on the following day he was engaged out to dinner, but was obliged to remain at home on account of increasing indisposition, and on Monday, the 13th, at

one o'clock, he was a corpse. He was in the 69th year of his age, in the possession of all his faculties, expecting perhaps to live many years, and still zealous for knowledge, being actually engaged in acquiring professional information when attacked by his fatal disease. He thought he might confidently assert that no man's death would have excited so general a feeling of sympathy and regret for his loss. The loss the Society had sustained by the death of its Vice-President, every gentleman in the room could estimate. His interest in this Society was great, he was one of the earliest to encourage its formation, and one of the most anxious of its members to promote its successful progress.

The President then referred to the literary labours of Mr. Crowfoot, and enumerated the various papers on medical subjects which had been written and published by him, and announced in conclusion that the vacant office would be filled at the next meeting.

The following specimens were exhibited:—

TUMOUR OF THE UTERUS.

Mr. Archibald Dalrymple stated that this tumour had been removed (*post mortem*) from a woman, aged 48 years. A suspicion of the disease existed 28 years ago, but more distinctly referred to the last ten. She suffered frequent hæmorrhage per vaginam, also great distress in passing the urine and feces, with deep-seated pain in the pelvis and down the legs. No examination could be made per vaginam, owing to congenital malformation. During the progress of the disease her symptoms became aggravated, and she became extremely emaciated; both lower limbs were at times anasarctous, the left one more particularly so at the time of death. Micturition could only be effected in the sitting posture, and the introduction of a catheter was very difficult. The tumour was of enormous size, and weighed twenty-one pounds. The walls of the uterus could be detected and separated from the mass of the tumour. The greater part of the tumour was solid, but in some places it was softened, and presented a different appearance. Two or three smaller tumours were developed externally, of a similar character. No microscopical examination had as yet been made of it, but it was considered to be of a malignant character.

PERFORATING ULCER OF THE STOMACH.

Mr. Firth stated that this specimen had been taken from one of the inmates in the County Lunatic Asylum, in whom peritonitis had produced death in thirty-six hours; it was unaccompanied by any sickness. The ulcer presented the usual characters. This was one of those cases, owing to the rapidity of its course, which, occurring under suspicious circumstances, after a meal, might have excited the suspicion of poisoning. Beyond a few leeches, no other depletory measures were employed.

DISEASED TRACHEA: CROUP.

Mr. Cooper, of Filby, presented a trachea diseased through croup, a plug of plastic matter occupying the tube. The patient from whom it had been taken was twelve years of age, and the disease ran its course in seven or eight days.

CEREBRAL ABSCESS, COMMUNICATING WITH THE MEATUS AUDITORIUS EXTERNUS.

Mr. R. Thompson had been requested to see a young man, aged 15, who was suffering from a large abscess, surrounding the upper and back part of the ear of the right side. There was profuse offensive discharge from the ear, which he found communicated with the abscess. The abscess was opened with relief to the patient. He died soon after. On examining the brain, slight congestion was remarked, but not to any great extent, and upon slicing it an abscess the size of a hen's egg was discovered in the middle lobe of the right hemisphere, which emptied itself into the auditory canal, passing into that passage through the petrous portion of the temporal bone. A probe could be passed without difficulty through the ear into the cerebral abscess. The left side of the brain was healthy. The father's history of the boy was that he had always had a discharge from the ear, but never complained of pain or headache; in fact, his general health was good till within a fortnight of his death, and his intellect unimpaired to the last. This case shews what destruction may be going on in so important an organ, without the intellects being affected, and without producing paralysis or coma.

Dr. Ranking read a paper on "Ulceration and Inflammation of the Os and Cervix Uteri." He commenced by referring to the importance of the study, the most favourable position for making an examination, and the choice of instruments. In the classification of the disease, he found it sufficient to acknowledge but two forms of ulcer—that accompanied by acute inflammation, and that in which the concomitant inflammation has become chronic, and has induced infiltration and induration of the surrounding parts. The mildest form of uterine ulcer is the erosion or simple removal of the epithelium; in this form the majority of non-specific ulcerations commence, though rarely seen, as it soon yields to simple measures. When an attempt at reparation ensues, granulations rise and come to the level of the mucous membrane, constituting the "granular" ulcer of authors. An exaggeration of the granular state, giving rise to exuberant but flaccid granulations, constitutes the "coxccomb" ulcer, and when the surface of this is so tender as to bleed on the slightest touch, it may be called the "fungous" or "bleeding" ulcer. The concomitant appearances in these ulcerations are different degrees of vascularity of the non-ulcerated surfaces, different degrees of engorgement and hardness of the tissues, as indicated to the touch, and discharges of various characters bathing the surface, or exuding from the interior of the cervix. In simple excoriation the os will not be materially increased in size, but will exhibit the bright red hue of recent acute inflammation, and the excoriation itself, as well as the entire upper part of the vagina, will be bathed by a thick creamy pus. The same is, doubtless, the case in the commencement of the granular form, but generally when this ulcer is met with, the acute symptoms have subsided, and the os and cervix have put on the more livid hue of chronic inflammation, the discharge becoming thinner and curdy. The long persistence of this form of ulcer, or its transformation into the "coxccomb" form, is marked by

considerable engorgement of the neighbouring tissues; the discharge is starchy and tenacious, and the pain, hardness, and cachectic state of the system, not infrequently give rise to the suspicion of cancer; and Dr. Ranking is not prepared to say that such lesions may not actually be the forerunner of cancerous degeneration. Dr. Ranking divides the symptoms into local, and general, or sympathetic; under the former may be classed pain and heat in the vagina, increased by sexual intercourse, pain in the sacral and inguinal regions increased by standing, &c., scanty or profuse and painful menstruation, persistent leucorrhœa, in many cases sterility or great tendency to abortion. The sympathetic phenomena are more numerous: external neuralgic pains, nervous headache, dyspepsia in one form or another, irritable and capricious temper, &c.

A favourable prognosis may for the most part be formed; and in the treatment of these cases absence from sexual intercourse is a *sine quâ non*, the recumbent posture is to be maintained, and the diet regulated by the health of the patient. With respect to the local treatment, Dr. Ranking follows the indications afforded by the existence or non-existence of inflammation, or engorgement of the tissues. In the simpler forms, hip-baths and emollients, followed by slight astringent vaginal injections; if there is much vascular excitement, leeches to the vulva or cervix, with injections of Decoctum Papaveris, of lead, and subsequently of a weak solution of nitrate of silver. In other cases the application of the caustic (in substance,) to the part, every four, five, or seven days, according to the severity of the case. If, however, there is considerable inflammation, engorgement, and induration, whatever be the form of ulcer, no good is to be expected of caustic until these conditions have been reduced by leeches and counter-irritation. As an adjunct to the local treatment, some medicinal alterative is required, the best is the bichloride of mercury in small doses in sarsaparilla. The absorption of the interstitial deposit will also be materially assisted by the local application of some form of iodine. In the more severe cases the alterative action of mercury is almost essential.

Foreign Department.

ON THE PANCREATIC JUICE, AND ITS INFLUENCE ON THE PROCESS OF DIGESTION.

By M. BERNARD.

(Translated for the Provincial Medical and Surgical Journal, from the Archives Générales de Médecine, Jan., 1849.)

Anatomists have long regarded the pancreas as an abdominal salivary gland, guided by the fancied analogy of the pancreatic juice with the saliva, but as I shall presently show, this comparison is not just, and is far from expressive of the real uses of the pancreatic secretion.

It is my intention to demonstrate by experiment that the pancreatic fluid is destined, par excellence, for the digestion of the neutral fatty matters contained in the food, and so fit them for absorption by the lacteal vessels.

I shall here narrate in detail the series of observations by means of which I arrived at this important and hitherto unsuspected use of the pancreas, and I shall merely state that this conclusion is the result of a long and patient study by experiments on living animals, some of which I shall briefly recapitulate.

[It is unnecessary to give the author's experiments in detail; they are some of those disgustingly cruel torturings of living dogs, for which our French neighbours are famous, and consisted in opening the abdomen, and searching for the pancreatic ducts, and obtaining the secretion by fixing a tube to them, after which the wounds were closed, and a fistula established. The unfortunate animals all recovered. The experiments related are three in number; one when digestion was commencing, one when in full progress, and the third during a state of abstinence.]

Physical and Chemical characters of the Pancreatic Fluid.—The fluid obtained in the foregoing experiments was of two kinds. 1. The *normal* pancreatic secretion obtained before any inflammation was set up. 2. *Morbid* secretion obtained after reaction had ensued.

The first kind of fluid is colourless, limpid, and viscid, and becomes frothy by agitation. It has no characteristic smell, but has a saltish taste similar to that of the serum of the blood. The reaction is invariably alkaline; exposed to heat it coagulates firmly and universally, and the same takes place with nitric, sulphuric, and muriatic acids. No precipitate is caused by dilute vegetable acids; no change is induced by alkalies, but these re-dissolve the precipitate formed by heat and acids.

From these results it would appear that the pancreatic fluid, as has already been shown by Magendie, Teidemann, and Gmelin, is of an albuminous nature, in fact the coagulated substance has every appearance of albumen, but as I shall show there is no physiological analogy between this fluid and albuminous fluid, and it is important that this should be known, as the solid matter is the active principle of the secretions. There is, however, not a complete resemblance between the pancreatic coagulum and albumen, for the former, if dried, will dissolve readily in water, the latter will not.

Morbid pancreatic juice is of a watery consistence, without viscosity, and sometimes opalescent or reddish. It is alkaline, but does not coagulate either by heat or acids.

The pancreatic juice is, without contradiction, of all the fluids of the body, the most subject to spontaneous changes. Exposed to a degree of cold, from 5° to 10° below zero, it may be kept several days, but at a temperature of 45°, the lapse of a few hours suffices to render it putrescent, and uncoagulable by heat. Its alkaline character, however, still persists. In summer this change sometimes takes place in a few minutes, for which reason there is great difficulty in obtaining it in a state for examination at that season. The deposit which occurs under the putrefactive change, contains microscopic crystals of margarine and margaric acid.

Physiological Properties of the Fluid.—I stated in the commencement of this paper that the special use of the

pancreatic fluid was to digest the neutral fatty matters of the food; this is readily shewn by mixing a portion of olive oil, butter, or suet, with the fluid, exposed to a gentle heat, when a perfectly homogeneous emulsion is the result. If this emulsion be preserved for some hours, it will be perceived that the fatty matters are not only dissolved, but are also chemically changed, in fact the neutral fatty matters and the alkaline pancreatic juices, form a whitish alkaline liquid at first, but after a few hours the mixture becomes distinctly acid, being converted into glycerine and a fatty acid. When butter is mixed with the pancreatic juice, the odour of butyric acid is distinctly recognizable.

It thus appears that the pancreatic fluid has the property of dissolving neutral fatty matters, and converting them into glycerine and fatty acid. This faculty is peculiar to the secretion in question, and is, as I have ascertained by direct experiment, not possessed either by the bile, saliva, gastric juice, serum of the blood, or cerebro-spinal fluid.

The experiments upon which the above conclusions are based, have been frequently repeated, and are so easy of execution as to be readily verified; but it is absolutely necessary to recollect the difference between *normal* and *morbid* pancreatic secretions,—the former alone possesses the properties alluded to.

Action of the Pancreatic Fluid in Digestion.—After what has been said it may be readily conceived that the action of the pancreatic fluid is determinate; in fact it may be shown by experiment that by forming an emulsion with the fatty ingredients of the food, these are placed in a condition favourable for lacteal absorption, by being converted into the homogeneous fluid known as chyle. If an animal (as a dog,) be destroyed when in full digestion of fatty substances, the fat globules will be found floating on the surfaces of the fluids in the stomach undissolved; but in the small intestine, below the point of entering of the pancreatic ducts, the fat no longer possesses its characteristics, but is converted into a uniform creamy fluid, coloured yellow by the bile. The lacteals are seen to be gorged with this fluid. I have also seen, that if the pancreatic ducts are ligatured, the fat passes through the small intestines unaltered, and the lacteals contain a limpid watery chyle, destitute of the creamy globule, which form part of the normal fluid.

Such an experiment is in itself sufficient to decide upon the functions of the pancreatic fluid, but the same fact may be shown in an elegant manner, and unaccompanied by cruelty, as I will proceed to show. It so happens that, in the rabbit the orifice of the pancreatic duct is situated some distance (35 centimetres,) below that of the ductus communis choledochus. If, then, this animal be made to eat some fatty substance, and afterwards carrots, or its usual food, and be then destroyed, the intestines will be found to contain two kinds of chyle; above the entrance of the pancreatic ducts, it is limpid and watery; below, it is creamy, as in the carnivorous animal.

If it be thus easy to demonstrate the true function of the pancreas, it may be asked how is it that this

function has not been before ascertained, and how is it that Sir Benjamin Brodie has attributed the chyli-fication of the fatty matters to the action of the bile? To solve this question it is necessary to examine the researches of Brodie, in opposition with those of Magendie, which are directly contradictory. Magendie notices the experiments of Brodie, who, after tying the ductus communis choledochus in cats, observed that the lacteals no longer contained fatty matter, but that the chyle was limpid and transparent. Magendie intending to verify this result, tied the common duct in dogs, but found that in spite of the absence of bile from the intestines, the chyli-fication of fatty matters still took place. This incongruity is explained by the fact, that in the cat the pancreatic duct anastomoses with the ductus communis choledochus before it opens into the intestine, so that in preventing the access of bile, Brodie, at the same time, cut off the supply of pancreatic juice. In dogs this anastomosis does not take place, and the flow of the pancreatic juice remaining unobstructed, the natural changes took place in the fatty matters of the food. The two sets of experiments, therefore, are not really contradictory, and both support the truth of my observations.

It has thus, I conceive, been satisfactorily demonstrated that the pancreatic fluid is destined, to the exclusion of the other intestinal fluids, to modify specially the neutral fatty ingredients of the food, and to convert them into a fluid fit for lacteal absorption. I have here examined the pancreatic fluid by itself, but it is my intention in a future essay to study its nature in conjunction with the bile, and to show that together they fulfil another part in the function of digestion. I may add, in conclusion, that these researches do not invalidate the observations of Bouchardat and Sandras, respecting the conversion of starch into glucose by the pancreatic fluid. This is one of the functions of that fluid; but it is one which it possesses in common with others, as the saliva, serum of the blood, &c., and other alkaline fluids. The emulsifying of the fatty matters is another and special property of the same fluid, which is not possessed by any other fluid in the animal economy.

General Retrospect.

ANATOMY.

NEW STRUCTURE IN THE GENITAL ORGANS.

Dr. Gordon Buck has discovered a new anatomical tissue connected with the penis, which consists in a membranous sheath investing that organ, and forming a continuation with the suspensory ligament above, and perineal fascia below. To display this structure the following dissection is requisite:—

The penis and scrotum are to be circumscribed by an incision at the distance of three fingers breadth all round, and crossing the perineum at the anterior margin of the sphincter. The dissection of the skin and cellular tissue is to be made towards the penis on the level of the fascia lata laterally, and of the perineal

fascia posteriorly, and carefully continued to the body of the penis, as far as the corona glandis. By this means the penis, as well as the suspensory ligament, is denuded of its loose investments.

An incision is then to be made along the dorsum of the penis, splitting the suspensory ligament, and extending forward to the corona, between the dorsal vessels and nerves. The adhesions along the dorsum are firm, and require careful dissection. The dissection being carried laterally, the entire corpus cavernosum is enucleated, the muscles of the perineum being raised with the sheath. It is now clearly seen that the suspensory ligament from above, and the perineal fascia from below and the sides, form one continuous membrane with the sheath, enclosing the corpus cavernosum in its cavity, and embracing the corpus spongiosum urethrae between two layers, one of which passes above, the other below it. The excavated base of the glans adheres inseparably to the outer surface of the sheath, while by means of its inner surface it caps the surface of the corpus cavernosum. The cavity formed by this sheath is limited by the triangular ligament posteriorly. That portion which covers the foremost muscles, and has been described as the superficial perineal fascia, arises laterally from the ascending rami of the ischium, and descending of the pubis as far forward as the symphysis, where the two layers meet and form the suspensory ligament; it also sends off membranous septa from its upper surface, which project between the accelerator and erector muscles, to form the triangular ligament, thus forming three independent sheaths, which are confounded anteriorly with the common sheath of the corpus cavernosum.—*Transactions of the American Medical Association.*

PRACTICAL MEDICINE.

THLASPI BURSA PASTORIS IN MENORRHAGIA.

In a case of menorrhagia which had resisted ergot, astringent injections, &c., M. Vanove employed a decoction of this common herb with complete success. The woman was exhausted to the utmost degree when this medicine was commenced. The formula used was a decoction of a handful of the fresh plant in three tea-cups of water, boiled to two; the dose was a cupful twice a-day. It appears that the herb is in common use among the German peasantry.—*Rev. Med. Chir.*, December, 1848.

SURGERY.

HOSPITAL GANGRENE.

Mr. Guthrie concludes his lecture on this subject by the following aphorisms:—

1. Hospital gangrene never occurs in insulated cases of wounds.
2. It originates only in badly ventilated hospitals, crowded with wounded men, among and around whom cleanliness has not been too well observed.
3. It is a morbid poison, remarkably contagious, and is infectious through the medium of the atmosphere applied to the wound or ulcer.
4. It is possibly infectious, acting constitutionally, and producing great derangement of the system at

large, although it has not been satisfactorily proved that the constitutional affection is capable of giving rise to local disease, such as an ulcer, but should an ulcer occur from accidental or constitutional causes, it is always influenced by it when in its concentrated form.

5. The application of the contagious matter gives rise to a similar local disease, resembling, and capable of propagating itself, and is generally followed by constitutional symptoms.

6. In crowded hospitals the constitutional symptoms have been sometimes observed to precede, and frequently to accompany, the appearance of local disease.

7. The local disease attacks the cellular membrane principally, and is regularly propagated along with it, laying bare the muscular, arterial, nervous, and other structures, which soon yield to its destructive properties.

8. The sloughing of the arteries is rarely attended by healthy inflammation, filling up their canals by fibrin, or by that gangrenous inflammation which attends on mortification from ordinary causes, and alike obliterates their cavities. The separation of the dead parts is therefore accompanied by hæmorrhage, which in large arteries is usually fatal.

9. The operation of placing a ligature on the artery at a distance, or near the seat of mischief, does not succeed, from the incision being soon attacked with disease, unless it has been arrested in the individual part first affected, and the patient has been separated from all others affected by it.

10. The local disease is to be arrested by the application of the actual or potential cautery:—an iron, heated red hot, or the mineral acids, (pure,) or a solution of arsenic or of the chloride of zinc, or other caustic which shall penetrate the sloughing parts, and destroy a thin layer of the unaffected part beneath them.

11. After the diseased parts have been destroyed by the actual or potential cautery, they cease in a great measure to be contagious, and the disease incurs less chance of being propagated to persons having open wounds or ulcerated surfaces. A number of wounded thus treated are less likely to disseminate the disease than one person in whom constitutional treatment alone has been tried.

12. The pain and constitutional symptoms occasioned by the disease, and considered as distinct from those symptoms which may be dependent on disease endemic in the country, are all relieved, and sometimes entirely removed, by the destruction of the diseased surface, which must, however, be carefully and accurately followed, to whatever distance, and into whatever parts it may extend, if the salutary effect of the remedies is to be obtained.

13. On the separation of the sloughs, the ulcerated surfaces are to be treated according to the ordinary principles of surgery. They cease to eliminate the contagious principle, and do not require specific treatment.

14. The constitutional or febrile symptoms, whenever, or at whatever time they occur, are to be treated according to the nature of the fever they are supposed to represent, and especially by emetics, purgatives, and the early abstraction of blood, if purely inflammatory,

and by less vigorous means if the fever prevailing in the country is of a different character.

15. The essential preventive remedies are separation, cleanliness, and exposure to the open air—the first steps towards that cure which cauterization will afterwards in general accomplish.—*Lancet*.

NEW TREATMENT OF CERTAIN FORMS OF BLOOD-TUMOUR.

M. Petrequin describes a particular form of sanguineous tumour, very similar in appearance, but different to common erectile tumour. It is found to be situated in the cellular tissue, not like the other in the skin, and consists of a cavity containing fluid blood, but destitute of any membrane or cyst. These tumours elevate the skin, but it does not become discoloured unless the distension is great. They are soft and fluctuating, and recognized with ease. In doubtful cases the diagnosis is rendered certain by means of an exploring needle. The more common site of this tumour is said to be the forehead. The author's treatment of this form of disease is by puncturing the tumour, withdrawing about a third part of the blood, and injecting in its stead a concentrated solution of citric acid; compression is then employed, and a cure is said to be effected in a few weeks.—*L'Union Medicale*, Oct., 1848.

TREATMENT OF HYDROCELE.

Dr. Marsh, of Albany, describes what he believes to be a prompt mode of effecting a radical cure of hydrocele. His operation consists in using a large-sized trocar and canula, through which, after evacuating the fluid, he introduces a camel's hair brush dipped in a solution of the iodide of potassium, and so brushes over the whole surface of the tunica vaginalis.

Dr. Horner, in addition to injecting the tunica vaginalis, introduces a few threads from top to bottom through the cavity, by which he considers that he ensures a more certain secretion of lymph and less of serum.—*Transactions of American Medical Association*.

SPINA BIFIDA.

Dr. Brainerd has treated this affection by injecting a grain of iodide of potass and half a grain of soda into the tumour, without evacuating the fluid in which it eventually becomes dissolved. As far as may be judged by a single case, this plan is attended by little or no danger.—*Id.*

ON THE USE OF CHLOROFORM IN SURGERY AND MIDWIFERY.

In a paper published in the *London Monthly Journal*, Dr. Snow has given a brief account of his experience respecting anæsthetic agents.

In comparing chloroform with æther, he states that either is capable of obviating the pain of the most severe operation, but that chloroform possesses certain advantages. In the reductions of dislocations and herniæ, he prefers æther.

Contrary to the opinion generally entertained, Dr. Snow does not consider its use contra-indicated in disease of the chest, unless of an active kind; neither

is it so dangerous in diseases of the heart as has been supposed. He, however, admits that in such cases it should be administered with caution.

Young subjects are most readily influenced, and immunity of pain may be accomplished without perfect coma. The greatest debility is no impediment to its use.

Dr. Snow objects to the plan of giving chloroform on a handkerchief. The stomach should not contain much food for fear of vomiting.

The greater number of patients become quietly insensible without resistance; some became excited while losing their consciousness, but by continuing the inhalation, this excitement is overcome. When voluntary motion or talking is no longer observed, it is desirable to examine the eye. If it be turned up, it is an indication of sufficient narcotism for ordinary purposes. When the margin of the eyelid can be touched without causing the orbicularis to contract, any operation will be painless. As the effect of the vapour is cumulative, Dr. Snow advises the free admission of air just previous to the production of insensibility.

The patient, after a severe operation under chloroform, is in a calmer and more cheerful state of mind than if he had suffered the pain; and after an amputation he seldom experiences nervous starting of the stump.

In midwifery, the dose of chloroform required is less than in surgical operations. If given with the handkerchief, not more than fifteen drops should be used at a time. Dr. Snow dissents from Dr. Simpson in this particular, the latter advising two or three drachms to begin with. The patient should be allowed to inhale a little at the commencement of each pain, but the insensibility need not be complete. Dr. Snow believes, that with management no retardation of the labour will occur, but, on the contrary, that it will be hastened by the relaxation of the soft parts which is produced.

OBSTETRIC MEDICINE.

USE OF ICE TO PROMOTE UTERINE CONTRACTION.

Drs. Mackale, Skinner, &c., speak highly of the power of ice to reproduce labour-pains when suspended. It is pounded and swallowed freely. Dr. Mackale says, "During two years I have had frequent opportunities of observing its effects, and in no instance have I been disappointed in its action. In cases where labour-pains had been suspended for twelve or twenty-four hours, they have been renewed promptly and efficiently. In cases of inevitable abortion, when the uterine contractions are feeble and inefficient, and hæmorrhage considerable, I regard it as invaluable."—*Transactions of American Medical Association.*

TREATMENT OF RIGIDITY OF THE OS UTERI DURING LABOUR.

Dr. Scanlon, who has carefully examined the conditions of the os and cervix, in the latter months of pregnancy, believes that the constriction, which sometimes declares itself in the first stage of labour, is due to rigidity of the upper orifice of the uterine neck, and

not the lower, which is generally sufficiently dilatable. Instead of the treatment usually recommended, viz., bleeding, antimony, belladonna, frictions, &c., he advises a continuous douche of warm water upon the os and cervix, directed by means of an appropriate instrument.—*Union Méd. and Rev. Méd. Chir.* Dec., 1848.

MEDICAL REFORM.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

The subject of Medical Reform, although one of the most important, as regards the Provincial Medical Practitioner, has not made its appearance in the columns of the *Provincial Journal* in a way that might have been reasonably expected, viewing, as we all must, its vast importance both to the profession and the public, more particularly, as it is to be presumed that the question will be finally adjusted during the present Session of Parliament. In the *Daily News* of Wednesday last, the 21st of February, is an article upon the subject, discussed in a way that carries conviction with it, the only error is that of stating that it is presumed that Mr. Wakley is on the side taken by the National Institute, which every member of the profession must know to be an error, as that gentleman has always taken an opposite view.

The article in question starts by saying that the year 1849 is to be the year of Medical Reform. It then alludes to the principles of the "Bill for Regulating the Practice of Physic and Surgery," agreed to by the Colleges of Physicians and Surgeons, and the Society of Apothecaries, and the National Institute of *General Practitioners*, which was noticed by the *Daily News*, when first issued. It goes on to say that at that time we stated our objection to these principles, as maintaining the old Colleges of Physicians and Surgeons, and constituting a new one for general practitioners, thus perpetuating distinctions in the profession, which have arisen out of purely accidental circumstances, and which, having no foundation, either in the sciences on which medicine, or its practice as an art, is founded, must exercise an injurious influence upon the medical profession, and inflict an evil upon the public. If, however, the medical men of Great Britain are willing to accept a measure of reform founded on these principles, we must leave them to themselves, and act as council for the public. We ask the members of the profession if the measures propounded in the principles will secure either to the practitioner in medicine his right position in relation to the State, or the most efficient medical aid to the public.

We have before pointed out the impossibility of drawing any legislative line between a physician, surgeon, or general practitioner, and the consequent inexpediency of legally perpetuating such distinction; our great objection to it is, that it will serve to perpetuate those jealousies and misunderstandings in the profession which have been the barrier to its own internal improvement, and to its public utility.

The members of the new College will be,—what it has ever been the policy of the Colleges of Physicians and Surgeons to make the surgeon-apothecaries,—an *inferior* class. This, we find, is denied by the National Institute; but they do not condescend to argue the point.

“The provincial practitioners must know very little indeed of the stuff of which the Fellows of the College of Physicians, and the Council of the College of Surgeons are composed, if they think that either body would consent to such an equality as that of which the Council of the National Institute seem to be fondly dreaming.”

If the provincial practitioner be not quite lost to all proper sense of justice due to the members of the healing art, and their successors, both as regards their proper position in society, and their usefulness to the public, they will be up and stirring at the present important crisis, and make a bold and determined effort ere it be too late to avert the deadly arm raised to strike the blow of destruction. Should (unfortunately,) there be so much apathy as to permit such a degradation, then, indeed, will the present generation of medical practitioners richly deserve all that may happen to them, and the curses of their children and their children's children will fall back upon them. Then we must, in order to protect ourselves from the nuisance, keep open shop, and retail lucifer matches, hair oil, quack remedies, &c., &c., as we then shall be associated with that class of persons in the same way that a person who is in company with tobacco smokers must smoke tobacco also; we then no longer can boast of our professional standing, but content ourselves to be petty shopkeepers. Surely such a state of things will never be permitted. Where is the President of the Provincial Association, one who stands high, and deservedly so, as a profound surgeon and practitioner in medicine and midwifery? Where are the surgeons of like reputation in Manchester, Liverpool, Leeds, Newcastle, York, and all the large cities and towns in England? They, I feel satisfied, have not paid proper attention to the subject; but I am sure something must occur that will fly with the rapidity of the electric telegraph through every nerve in their bodies, which will induce them to hold meetings, with a view of loading the Government with petitions to avert such a serious evil. A meeting, I believe, will shortly take place in London, for the purpose of collecting all our forces, to upset the one-sided evidence given before the Medical Registration Committee last Session, at which meeting, delegates should attend from all parts of the provinces.

Surely the large body of Members of the College of Surgeons will not quietly submit to insult upon insult, degradation upon degradation. The Council of the College of Surgeons have already heaped upon the provincial members a vast amount of insult and degradation by their recent Charter, and they now are endeavouring to double it by encouraging all in their power the inferior institution of general practitioners. They in the first place objected that *that* institution should examine in surgery, but afterwards assented, upon condition that all the candidates should undergo

an examination at the College of Surgeons, and pay the fee, but to be registered in the College of General Practitioners, thus receiving the fee and immediately casting him off; for future practitioners will have neither voice nor interest in the College of Surgeons, nor will that institution have any regard for its members, and what still further proves the fact of the inferiority of the College of General Practitioners, is the fee of £5 for a physician or pure surgeon, £2 for a general practitioner. What can be more conclusive? The inference must be, that, being an inferior grade of practitioners, a less fee is required; and it appeared also evident that the College of Physicians is determined to prevent gentlemen from obtaining that degree who have been practising generally. Look at the recent case of Dr. Crisp, one of our own body, a member of the Provincial Association, who, submitting to a most trying examination, was rejected, without any satisfactory reason being given. No doubt, had a college graduate been submitted to a fractional part of such an examination, he would have passed with great *éclat*.

I am, Sir, your obedient Servant,

GEORGE BOTTOMLEY.

Croydon, March 1st, 1849.

ANÆSTHETIC EFFECTS OF THE CHLORIDE OF OLEFIANT GAS.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

As since the last notice of the effects of chloride of olefiant gas, a fair practical test has been given to the liquid, it may not be improper to shortly mention the cases. The first was a case of exceedingly rigid os uteri, in a very delicate woman, with a troublesome cough, and very cedematous legs, but with a pelvis well formed. For three hours, the pains being strong, and very little dilatation produced, twenty minims of the fluid were put upon a handkerchief, and at intervals of five minutes, ten minims were put upon it twice; in all, 40 minims. Almost *instantly* dilatation began, and in fifteen minutes the child was born. The lady was not rendered completely unconscious, (which, I believe, to be very rarely necessary, and always, if possible, to be avoided in midwifery,) but was very happy, forgot her sufferings, and began to tell that which was uppermost in her mind.

The three following cases were patients in the Leeds Infirmary, and I am indebted to the kindness of my friends, Messrs. Smith, Teale, and Hey, for the opportunity of giving it to them.

The first was a man, 55 years of age, who had had for some years so great contraction of the adductor muscles of both thighs, as almost to fix the extremities. Forty minims were given upon a cloth, not held at first very close over the face. Before becoming unconscious he muttered and moved a little. Twenty minims more were given, when he became perfectly unconscious, with relaxation of the muscles. This was kept up by

another twenty minims, which had the effect of continuing the anæsthesia. During the time forcible abduction was gradually made, with considerable improvement to the power of separating the legs. Eighty minims were given in all.

The next was a woman, aged 42, in whom a small malignant tumour was removed from the side. Forty minims were given, which at once put her into a complete condition of anæsthesia, without uttering a word, or moving at all.

The third patient was a boy, 15 years old, who, from malformation of the lower extremities, had the inner hamstring muscle of both legs divided. He had thirty minims given at first, then twenty, and afterwards ten, in all, sixty. He was not so quiet as the woman, but altogether unconscious, even when put to bed, although the operation and dressing, &c., necessarily occupied some time.

In none of these four cases was the least irritation or cough produced, and neither at the time, nor afterwards, was there any unpleasant symptom of any kind. I need not mention that a much larger quantity of chloroform would have been required to produce a similar condition, and would only further add, that I believe the little uneasiness witnessed in the man before passing into a state of complete anæsthesia, arose from the quantity of Dutch oil given not being quite sufficient, but until the exact effect of it was known, I preferred giving too little rather than too much.

I am, faithfully, yours,

THOMAS NUNNELEY.

Leeds, March 15, 1849.

THE LONDON AND PROVINCIAL MEDICAL DIRECTORY, AND MR. DAWSON'S PAMPHLET.

[At the request of some of the parties whose names are mentioned, we copy the following correspondence from the *Lancet* of March 17th.* The pamphlet is altogether beneath notice, but for the unwarrantable use made of the names of gentlemen of character. The writer is already known by the equivocal laudations of a person of the name of Teevan; his present manœuvre would seem to be to force attention to his productions by an attack on well-known members of the profession.—Ed.]

THE DAWSON PAMPHLET.

The editors of the *London and Provincial Medical Directory* present their compliments to the editor of *THE LANCET*. Their attention having been drawn to a pamphlet entitled, "The London and Provincial Medical Directory Unmasked," they wish to state that it is true Dr. Tyler Smith was one of the originators of the *Medical Directory*, in 1845, and took part in the compilation of the volume for that year; but on the

10th of April, 1845, he disposed of his share in the work, and since that time has never in the slightest degree interfered with, or been concerned in, the production of the volumes of the *Directory* for 1846, 1847, 1848, and 1849.

The omissions in the *Directory* for 1849, of which Mr. Dawson complains, arose solely from the desire of the editors to be correct. As his return was not found to correspond with the list of the College of Physicians, a letter was addressed to the registrar, inquiring into the matter. The reply of Mr. Sedgwick, the secretary to the college, is subjoined, and at once affords a vindication of the endeavour of the editors to be as correct as possible, and gives, at the same time, the *true and only reason* for the omission of the qualification adverted to by Mr. Dawson.

Beaufort-buildings, Strand, March 14, 1849.

(Copy.)

College of Physicians, Nov. 15, 1848.

Mr. Sedgwick presents his compliments to the editors of the *Medical Directory*, and in answer to their note, addressed to the registrar, begs to inform them that there is no such name either as Richard or Samuel Dawson on the College list.

There was, a few years since, a gentleman of the name of Richard Dawson, an *extra licentiate*, but his name was struck off the list.

Mr. Sedgwick thinks that the Richard and Samuel Dawson mentioned by the editors, are *one and the same person*.

To the Editor of *THE LANCET*.

Sir,—In reference to a pamphlet which has been extensively circulated, and which contains sundry scurrilous remarks, I beg to state, that so far from there being any collusion between Dr. Tyler Smith and myself, we were, in consequence of family matters, upon which it is unnecessary to enter, on unfriendly terms from the beginning of 1846 till the commencement of 1848, the time to which the statements of Dawson refer. During this period, no communication of any kind passed between us. I write this in justice to Dr. Tyler Smith and myself. It is, however, very evident that the purpose of Dawson is to recommend his pamphlet on "seminal discharges," "nocturnal pollutions," &c., and that the absurd introduction of Dr. Tyler Smith's name merely forms an excuse for Dawson's addressing himself to the respectable members of the profession.

I am, Sir, your obedient servant,

JAMES YEARSLEY.

Savile Row, March 13, 1849.

To the Editor of *THE LANCET*.

Sir,—A pamphlet has been sent to me, bearing the signature of "R. Dawson, M.D.," in which a most unwarrantable use is made of my name in connexion with that of Dr. Tyler Smith. I beg to say, emphatically, that in *no one particular* is the statement which relates to myself and Dr. Smith *true*.

I am, Sir, your obedient servant,

WM. HARVEY.

Soho Square, March 13, 1849.

* The letters are published also in the *Medical Gazette* and the *Medical Times*.

Medical Intelligence.

APPOINTMENTS.

Paris Thomas Dick, M.D., has been appointed Physician to the Bedford General Infirmary, in the room of Dr. Witt, resigned.

James Turnbull, M.D., has been elected Physician to the Liverpool Infirmary, in the room of Dr. Freckleton, resigned. Dr. Freckleton has been appointed one of the Consulting Physicians to the Institution.

John Thurnam, M.D., of the Retreat, near York, has been appointed Medical Superintendent of the Wilts Lunatic Asylum.

Nathaniel Ward, Esq., has been elected Assistant-Surgeon to the London Hospital.

ROYAL MEDICO-CHIRURGICAL SOCIETY.

The following gentlemen have been elected Officers of this Society for the ensuing Session:—President—Thomas Addison, M.D. Vice-Presidents—Henry Davies, M.D.; George Burrows, M.D., F.R.S.; George Macilwain; Samuel Solly, F.R.S. Treasurers—James Alderson, M.D., F.R.S.; Benjamin Phillips, F.R.S. Secretaries—William Baly, M.D., F.R.S.; Fred. Le Gros Clark. Librarians—John Hennen, M.D.; James Dixon. Members of Council—Robert Nairne, M.D.; William Sharpey, M.D., F.R.S.; Leonard Stewart, M.D.; Seth Thompson, M.D.; Charles J. B. Williams, M.D., F.R.S.; Sir B. C. Brodie, Bart., F.R.S.; James Bird; William Fergusson, F.R.S.; Samuel A. Lane; James Paget.

UNIVERSITY OF OXFORD.

The Degree of Bachelor of Medicine has been conferred on Charles W. Eddy, Esq., of University College, one of Dr. Radcliffe's Travelling Fellows.

SOCIETY OF APOTHECARIES.

Gentlemen admitted Licentiates, Thursday, March 1st:—John Prowse, Somerset; Wm. Webb, Shrewsbury; Thomas Crowther, St. John's, near Halifax; Richard Skinner Heming, East Brent, Somerset; Thomas Harrison Marshall, Kingston-upon-Hull; Frederick Whitborn, Epsom; Freeman Izod, Esher.

Gentlemen admitted Licentiates, Thursday, March the 8th:—Francis Fawcett Welsh, Saffron Walden; Henry Payne Leech, Bury St. Edmunds; Frederick Oughton, Camberwell; Fred. Montgomerie Davenport Davidson, Dawlish; Wm. Henry Johnson, Weymouth.

OBITUARY.

Died, February 23rd, at Islington, aged 48, Edward Roe, Esq., Surgeon.

February 26th, in Keppel Street, Russell Square, aged 51; Leonard Stewart, M.D.

March 8th, aged 83, Robert Rainey Pennington, Esq., Senior Fellow, and one of the oldest Members of the College of Surgeons, his diploma being dated 1787. Mr. Pennington was President of the National Institute of Medicine, Surgery, and Midwifery.

March 9th, Anthony White, Esq., Member of the Council, and twice President of the Royal College of Surgeons.

March 10th, at Wavertree, in the 74th year of his age, John Latham, Esq., Surgeon.

Lately, aged 57, after a long and painful illness, Dr. Michel Fodera, professor of physiology at the University of Palermo, well known by his works on the Special Nerves, and on Absorption.

BOOKS RECEIVED.

TO CORRESPONDENTS.

Communications have been received from Mr. Humpage; Mr. Humphry; Dr. J. Davies; Mr. Leach; Mr. W. Peck; Mr. Bottomley; Mr. Nunneley.

It is requested that all letters and communications be sent to Dr. Streeten, Foregate Street, Worcester. Parcels and books for review may be addressed to the Editor of the Provincial Medical and Surgical Journal, care of Mr. Churchill, Princes Street, Soho.

PROVINCIAL MEDICAL & SURGICAL JOURNAL.

CLINICAL LECTURE ON ALBUMINURIA.

DELIVERED IN THE

LEEDS PUBLIC DISPENSARY.

By J. D. HEATON, M.D., Senior Physician to the Dispensary.

I shall select for our consideration in this lecture, some cases which have occurred in the practice of this Institution, of the disease now generally called albuminuria, serving to illustrate several important practical points in the progress and treatment of the disorder.

The first case I shall notice is that of Charlotte Carter, aged 27, who is still on our books, though on the point of being discharged. She was admitted on the 2nd of October last. A large stout woman, usually of a rather florid complexion, said to be of regular and temperate habits; she is married and has had four children. The last child was born twelve months since; it died when five months old. Since its death she menstruated once, and then became again pregnant. She thinks she is now in the fifth month of her pregnancy.

She has been out of health since about the time of the death of her last infant; she then became subject to pain in the loins, and observed that her feet began to swell. Since then the feet have always been œdematous; she has never perceived any swelling of the face. It is only about three weeks since she felt herself seriously ill; she then had much pain in the loins; the urine became very scanty, turbid, and of the colour of blood; and she began to swell much more than she had done before. She has not had medical advice before applying at the dispensary. She has had some œdema of the feet during former pregnancies; but not at all to the extent she has now; nor has the whole body been swollen. She has been visited and prescribed for by our visiting assistant for a few days before I saw her, which was on the 9th. She was then very extensively anasarcaous; the legs were very œdematous; the abdomen contained much fluid; and the breasts were remarkably distended and tense, with a glazed erythematous state of the skin, and very painful and tender. She is obliged to have the breasts supported by a sling. She is so much swelled all over as to have great difficulty in turning in bed; large folds of the skin are formed between the thigh and the groin which have become excoriated by intertrigo, and partly perhaps by the dribbling of urine, which she has

much difficulty in voiding, both from her almost inability to assume a convenient posture, and from the œdematous distension of the parts. She has occasional pain in the loins, not so severe as at the commencement of the attack. Pulse 100, small and soft; tongue quite healthy in appearance; urine abundant, pale, rather opalescent, but only depositing a cloud of mucus; specific gravity only 1005; moderately albuminous. She is in good spirits and the appetite is not very much impaired.

E lumbis detrahantur sang. viij. ope c. c. R. Ol. Crotonis, gtt. ij.; Extr. Nucis Vomicae, gr. j.; Micae Panis q. s., ut fiant pilulæ ij. Sumat j. omni mane.

R. Tincturæ Cantharidis, dr. j.; Infusi Digitalis, oz. viij. M. Sum. unciam quater quotidie.

September 11th. She has had less pain in the loins since being cupped; thinks she makes more water than she did, the urine has now a specific gravity of 1010, and is less albuminous than before; the bowels have been freely purged; pulse 88; other symptoms as before.

Omitt. pilulæ. Omni mane sumat Potassæ Bitartr. dr. ij. Cont. mistura.

12th. The breasts are much less tense but other parts appear equally distended as before. Bowels not much acted on by the Potassæ Bitartras. Makes less urine than yesterday.

Addæ Misturæ Tinctr. Scillæ, dr. ij.; Tinctr. Ferri Sesqui-Chloridi, dr. iss. Postridie mane sumat Pilulæ Croton. ut antea.

16th. There is considerable improvement since last report; she makes more urine, and the dropsical effusion is reduced in all parts of the body.

19th. Since last report, she has taken another croton-oil pill, which each time produces several watery evacuations, and gives much relief. The swelling is now much reduced. She is able to leave her bed and attend to some of her domestic employments. The urine is of average quantity, opalescent as before, specific gravity raised to 1015, and now gives only a very slight cloudiness on the addition of nitric acid.

During the following month she continued the use of the same means, taking a dose of cream of tartar each morning, to which (as it did not act much on the bowels by itself,) a small proportion of jalap was added; for which powder the croton-oil pill was substituted once or twice a week. There was still a slow gradual improvement; the dropsical effusion became limited to the feet, where her advancing pregnancy

might alone occasion it. She has occasional pain in the loins, which sometimes extends into the left ilium, but her strength and appetite improve, and she can follow her customary avocations. The mixture was changed for the following:—

R. Tinct. Ferri Sesqui-Chloridi; Acidi Nitrici Dil., utr. dr. ij.; Inf. Diosmæ, viii. oz., Sumat oz. j. quater quotidie.

But this did not agree: the urine became more scanty, there was more œdema and more pain in the loins. Adde Misturæ Tinct. Hyoscyami, dr. ij.; vice Acid. Nitric. Dil.

With this change her medicines seemed quite to agree and to operate favourably. The last two or three times that the urine has been examined it has presented no traces of albumen; and her general health is so good that she would have been discharged but for her own wish to be allowed to continue the use of the powders and mixture, which she thinks continue to be beneficial to her.

Frances Dent, admitted February 18th, a middle-sized woman, of rather dark but faded complexion, aged 42. She is married; was delivered twelve months since of a dead child, after hard labour. She has been out of health since then, though with no very definite complaint till the present attack. She has menstruated regularly since her confinement. She has had no pain in the loins, except during the menstrual periods, when she always has this; she has not observed anything remarkable about the urine. She menstruated last a fortnight since, when the discharge was excessive and continued longer than usual. Some days after this commenced she began to swell in the face, legs, and abdomen; she had a frequent desire to make water, requiring her to rise in the night several times. She had not more pain in the loins than usual, but had an unusual pain in the lower part of the abdomen.

My first visit was on the 24th, when I found the face and legs œdematous, the abdomen large and flabby, but presenting no distinct fluctuation; considerable tenderness in the loins, but no pain at present without pressure; pain in the hypogastrium; headache; drowsiness; loss of appetite; tongue large, covered with a thin moist white coat; frequent micturition; urine pale, opalescent, but without a distinct deposit, of average quantity, specific gravity, 1015, very slightly alkaline, highly albuminous; pulse rather frequent.

E Jumbis detrahantur, ope c. c. sang. oz. viij. Omni mane sumat Potassæ Bitartr., dr. ij. R. Inf. Diosmæ, O. j.; Tinct. Cantharidis, dr. j.; Sp. Æther. Nitr., dr. ij. M. Sumat oz. ij., quarta quaque hora.

28th. Swelling of the face much reduced; legs still very œdematous; urine more copious, but not materially altered in its properties; tenderness but no pain in the loins; bowels not moved. Omni mane sumat pilulum cum Extr. Elaterii., gr. l-6th, vice Potassæ Bitartr. Repetatur mistura.

March 10th. There is much improvement since last report. Each pill has produced about three liquid stools, with much sickness, but without griping. She

finds that the urine passed in twenty-four hours amounts to about three pints; it is pale and clear, specific gravity, 1015, slightly alkaline; much less albuminous than when examined before; boiling only causes a slight opacity, the addition of nitric acid much increases the coagulum. Pergat sed adde Misturæ Potassæ Acetatis, dr. iij.

14th. Not much change of symptoms, except that the urine is more abundant, the patient having passed nearly lb. vj. in twenty-four hours. Some days the face is much swelled, at other times not so. Omitt. pilula. Rep. mist. omitta Potassæ Acetate.

18th. Feels generally better; the appetite is improved; tongue natural; pulse slow and feeble; legs still œdematous; face occasionally swelled; urine very copious, still albuminous; pulse feeble and slow; appetite poor. Quater die sumat, Tinct. Ferri Sesqui-Chloridi, gt. x., in aqua. Pro re nata sumat Pil. Colocynth. Co., gr. x. Omitta Pilulum Elaterii, et Misturam Diosmæ.

24th. She is much improved since last report; she is able to rise and come down stairs; legs much less swollen, though still somewhat œdematous. Feels her general health much better; appetite much improved; tongue clean; urine about lb. iv. per diem.

After this she went into the country, where I understood that she continued better, but the œdema never left the ankles.

June 13th. She again applied at the dispensary very dropsical, and suffering from much dyspnoea and pain at the epigastrium. Urine very scanty, not above eight ounces per diem, of a low specific gravity, and highly albuminous. She was ordered purgative medicines, and a diuretic mixture, containing acetate of potash and tincture of cantharides. I saw her once afterwards, when she was somewhat relieved, but still very ill. After this I again lost sight of her till September, when she presented herself at the dispensary, professing to be quite well. She had been again out of Leeds during the interval. She certainly looked very much better; she had gained flesh, and had a more healthy complexion than I had seen before; there was no œdema about the ankles; she said the urine appeared natural; the appetite was good; she felt quite well, and wished to be discharged. Before discharging her, however, I told her to bring me some of her urine for examination, which I found clear, pale, slightly acid, of a specific gravity of 1020, but *strongly albuminous*. It was evident the disease still remained, though latent for the present, and ready to re-appear on the occurrence of any exciting cause; but as she required dismissal, I discharged her, and have seen nothing of her since.

These cases serve to give a fair representation of the ordinary symptoms and progress of a more chronic form of the disease now usually called albuminuria, from one of its most characteristic and essential symptoms. The seat of this disease is the kidneys, as is clearly proved by *post-mortem* examination of fatal cases; and one name, which is used as synonymous with albuminuria, is granular degeneration of the kidney, which refers to the peculiar appearance

presented by this organ in those who have died of this disease. The changed condition of the urine would not *alone* be a sufficient proof that the kidneys were chiefly in fault, for we have many instances of morbid states of this excretion where this is not the case. Changes in the condition of the blood must alter the character of the urine, whose materials are derived therefrom, whether these be merely temporary, as from some change of diet, or some derangement of the digestion, or general health, or whether they be of a more permanent character, as in diabetes, or lithiasis, where we have permanently morbid states of urine produced but the kidneys are not the seat of the disorder.

Albuminuria may frequently be found to commence with some exposure to cold and wet, which has the effect, when long continued, of repelling the blood from the surface, and causing it to be unduly accumulated or congested in some internal organ; any organ predisposed to a congestive or inflammatory state, whether from an habitual atony of its vessels, or from some actually pre-existing disease, being that most likely to suffer. Thus some persons are liable to have an attack of quinsy, others of catarrh, and others of diarrhœa, from a similar exposure to cold. It is as true with regard to vital as it is to physical phenomena, that the same cause, acting under the same circumstances, must produce the same effects; so that when we observe the uncertainty of the results upon the bodies of our patients of the same causes, whether these be such as tend to derange the health, or remedies intended for its restoration, it is because of variations in other circumstances of the individuals, and which certainly exist, though we may frequently be incapable of recognizing them. These other circumstances which co-operate with some exciting cause of disease to determine what shall be the exact nature of the malady which results, are called predisposing causes. Various habits and conditions of body are observed to predispose to albuminuria; habitual intemperance, especially spirit-drinking, gives a strong predisposition, deteriorating the quality of the blood, and thus impairing the nutritive function. It is frequently found also in connection with those diseases of the heart which interfere with the free transmission of the blood through that organ, thus causing congestion of the abdominal organs. Again, in the female, albuminuria has been observed frequently during the state of pregnancy, more especially in those who have been subject to a rapid succession of pregnancies, which frequently has a marked effect in lowering the health, and inducing a thin innutritious condition of the blood, which may lead to those diseases connected with imperfect nutrition, such as scrofulous affections, tubercular disease of the lungs, cirrhosis of the liver, or granular degeneration of the kidneys.

In the first case we have noticed, we find albuminuria coexisting with a pregnancy which had speedily followed a previous confinement. But the nutritive functions do not seem to have been much impaired; she was still stout and well fed, and not without colour in the cheeks; neither had she been of intemperate habits; nor did other probable cause appear beyond the

condition of pregnancy. Perhaps the disease had existed during former pregnancies; she had had during those some œdema of the feet, but this is so common in pregnancy, merely from the mechanical pressure of the uterus upon the large veins of the abdomen, that no strong presumption can be drawn from this. There can be little doubt that the kidneys had been affected from the time when pain in the loins was noticed, seven months before admission; we must regard the case, therefore, as one of a rather chronic character, slowly progressing for some months, till, under the influence of exposure to cold, or some other disturbance, the nature of which is not recorded, the symptoms assumed a more active character about the time when she came under treatment.

When the disease assumes an acute form, there is usually a good deal of inflammatory fever, and pain in the loins, the kidneys being then inflamed or much congested; and even cases decidedly chronic may present temporary exacerbations of this kind occasionally supervening. But there were no very acute symptoms in this case; and the pregnant condition is unfavourable to very active treatment. A moderate local depletion, therefore, to relieve the hyperæmia of the kidneys, was the only loss of blood that the case seemed to require or admit of. Diuretics were ordered still farther to relieve the kidneys, by increasing the flow of urine, and at the same time to promote the excretion of the natural constituents of that fluid, which prove so very injurious if suffered to accumulate in the blood. When there are symptoms of much increased vascular action in the kidneys, the more stimulating diuretics are dangerous, though in the chronic form of the disease they may be very beneficial. The great distension of the body with extravasated serum, and especially the tenseness and erythematous appearance of the breasts, required the adoption of some further means for their relief, and for this purpose none are so efficacious as those which promote a copious watery secretion from the extensive surface of the intestinal canal. The use of active purgatives in this disease requires some caution, as there is not unfrequently a tendency to diarrhœa, of an intractable character, which, when once brought about, it may be difficult to arrest. The state of pregnancy, likewise, was another reason for caution in their use in this instance. They proved, however, so harmless upon trial, and were attended with such evident relief and subsidence of the swelling, that the patient requested to be allowed to continue their use. Having tried various medicines for this purpose, I find none more convenient than croton oil, which produces copious evacuations, and with less sickness and discomfort than are caused by elaterium. Some of the neutral salines, as sulphate of potash, are likewise useful for this purpose; these should be given in rather a concentrated solution, which then determines an endosmosis of the watery part of the blood into the intestine from the blood-vessels, which, thus deprived of their natural tension, become actively absorbent of the dropsical effusion which they had before allowed to escape. But if the saline be given much diluted, or, what is in effect the same, if followed by much diluent

drink, it then enters the blood, and acts upon the kidneys. Cream of tartar is likewise useful as an hydragogue purgative of mild operation, when given in full doses, and what enters the blood acts favourably upon the kidneys.

By these means the more urgent symptoms (the pain in the loins and the dropsical distension,) were relieved; the urine also had acquired a higher specific gravity, which—as it was not diminished in quantity, and contained much less albumen,—showed that the kidneys were now more efficiently excreting the solid constituents of the urine, and that that perversion of their function which allows the escape of the albumen of the blood, was likewise under correction. As there were no febrile symptoms, it now became expedient to attempt the improvement of the general health by a more tonic plan of treatment; for this purpose, and in this disease, no medicines are equal to the preparations of iron, and of these I know none so suitable as the tincture of the muriate, which combines diuretic with its chalybeate properties. In many cases I have found most marked benefit from the use of this remedy, both to the general health of the patients, and in producing a more healthy condition of the urine, which is the best proof of actual improvement. The effect of this disease upon the blood is very marked and characteristic; besides the accumulation in the blood of urea, which should be excreted by the kidneys, and the diminished proportion of albumen in the serum, there is a very great reduction in the amount of red globules which it contains. This is evident in the pale leucophlegmatic appearance of those who have been long the subjects of albuminuria; and we know that no medicine has an effect equal to chalybeate preparations, in restoring the red globules to blood in which they are deficient.

It is a question whether this patient be now completely cured, or whether the present improvement be only temporary. The total disappearance of albumen from the urine is a very favourable circumstance; we can hardly expect all serous infiltration to leave the feet till after her delivery. When the disease has not been of very long continuance, and the structure of the kidneys is not materially altered, these organs may still remain capable of performing their function efficiently, and with due care on the part of the patient to avoid injurious influences, and to maintain a good state of the general health, a cure may be permanent; but any degree of that change of structure in the kidneys, which is the essential part of the disease, must give a strong predisposition to a recommencement of the morbid action, and a return of all the symptoms. We consider the prognosis of albuminuria occurring in the pregnant female, and not known to have existed previously, as more favourable than under other circumstances. It is an observation of M. Rayer, that albuminuria may occur in pregnant females dependent upon a temporary hyperæmia of the kidney, without permanent change of structure; but we find, likewise, that the albuminuria appearing during pregnancy, may continue afterwards, or reappear, and prove as serious a disease as in other cases. We cannot, therefore, speak at all positively of the permanence of this cure, but at

present the result is quite as favourable as we may expect to obtain in a case which may be shown to have extended over several months.

The case of Dent a good deal resembles that we have just been considering, only that the cure was not so complete and satisfactory. It was not, in this instance, accompanied with pregnancy. Most probably the disease had existed for some time before admission, though she had only noticed the symptoms for a fortnight previously. The morbid change in the kidneys often goes on for some time unsuspected, though if the urine were tested it would be found albuminous; and the dropsy is the first symptom which attracts attention. When the urine passes to a highly albuminous condition from the healthy state within a fortnight, and the body becomes anasarous, we have more acute symptoms than presented themselves in this case,—such symptoms as we shall find in the next cases that we shall consider. There is, in such a case much inflammatory fever, pain in the loins, and the urine is very scanty and high coloured. But such was not the case in this instance; I conclude, therefore, that the disease had been gradually invading for some time. This being so, the prognosis was from the first less favourable, for probably the kidneys had already undergone a considerable degree of disorganization which can never be repaired. The acute form of the disease is attended with more immediate danger to life, but there is much more probability of permanent recovery.

The treatment of this case was very similar to that of the last, and so will not require much discussion. There were less symptoms of any vascular excitement of the kidneys in this than in the former case; there was no pain in the loins, though some tenderness, which is very generally present throughout the disease; no marked symptoms of febrile action, and the urine instead of being scanty, high-coloured, and turbid with the lithates, was pale, of average quantity, and opalescent. This opalescent appearance of the urine, I may remark, is very common in chronic albuminuria, the urine not being perfectly transparent, though presenting no visible turbidity, or allowing a precipitate to subside. It is found, on microscopic examination, to be owing to an excessive quantity of the epithelial scales of the secreting tubules of the kidneys, which, in this disease, are thrown off too freely. This being the case, I see that I ventured upon a stimulating diuretic from the first, having premised a moderate local depletion; for, although the urine contained a large proportion of albumen, its specific gravity was below the average standard, showing that its proper constituents were imperfectly excreted. Hydragogue cathartics were likewise employed, as in the former case, to promote the removal of the dropsical effusion, and subsequently the same chalybeate as in the former case was employed, to improve the quality of the blood, and corroborate the general health. The subsequent history of the case shows a relapse, and again a partial recovery, but the albuminous condition of the urine still remaining is evidence that the apparent recovery is fallacious. These chronic cases may

extend over several years, with occasional amendments, followed by relapses upon any derangement of the general health. They may terminate either by the occurrence of a low form of inflammation, attacking some important organ to which the condition of the blood seems to afford much predisposition, or more gradually, with increasing dropsical distension, oppressive dyspnoea, and a soporose or comatose state, before the fatal event. The reports of this institution would furnish many cases of this kind, but I have not taken one for consideration, as the progress of such cases, till approaching dissolution, are very similar to that last mentioned.

(To be continued.)

OBSERVATIONS ON SCURVY

AS IT WAS DEVELOPED
IN BATH AND ITS NEIGHBOURHOOD, IN
THE SPRING OF 1847.*

By JOHN BARRETT, Esq., F.R.C.S.

(Read at the Quarterly Meeting of the Bath and Bristol Branch of the Provincial Medical and Surgical Association, December 21, 1848.)

A question of very great importance is, what are the external circumstances which produce scurvy, and very different views have been held on this point. I believe the most common view, and the most correct one, is, that it is the absence of an organic acid in the food. There are some facts strongly corroborative of this opinion. In Dr. Shapter's cases there was either an entire absence, or very deficient quantity, of potatoes and vegetables, used as diet; and he says,—“From all that has now been stated, we must come to the conclusion, that the recent occurrence of scurvy in Exeter is due to this one cause,—a deficiency of food containing acid principles, and that the potato has hitherto been the means whereby these acid principles have been supplied.” He adds, in a note,—“It must not be understood from this that scurvy is stated to be solely caused by a deficiency of vegetable food; scurvy is essentially a disease of depraved nutrition, and may be produced by a too restricted and exclusive use of any kind of food. In this paper I am strictly confining myself to the nature and origin of the disease now prevailing.”—*Provincial Journal*, 1847. p. 285.

In the scurvy at the Cape, as described by Dr. Murray, the soldiers had plenty of good fresh meat, but not of fresh vegetables, and yet it occurred.

When the scurvy appeared at the Milbank Penitentiary, in the year 1840, it attacked one class of the prisoners, entirely sparing others who were longer under confinement; and it is shown that this exemption of one class of prisoners from disease “could only be attributed to their weekly diet containing five pounds

of potatoes, and an onion;” and after the potato was used generally, the scurvy entirely ceased. To those affected, “three oranges were ordered daily for each prisoner, besides nutritious food.” Dr. Baly, who gives this report, brings forward a number of instances from the reports of the inspector of prisons, showing that where the diet has been devoid of fresh vegetables, and the potato, though otherwise not deficient or bad, there the scurvy has prevailed, disappearing when the potato has been used. “At the Huntingdon Gaol, the diet which hitherto consisted of fourteen pounds of bread, ten pints of milk porridge, and four pints of soup, made of meat and vegetables, has been improved by the addition of solid meat, but no increase appears to have been made in the vegetable portion of the diet. The last report of the prison inspector mentions that scurvy still occurs.” A man and his wife were under my treatment at the same time; they were not badly off; could afford, and did have, meat every day, but potatoes and fresh vegetables, from their high price, they had denied themselves for some months. They both recovered under the use of citric acid and plenty of fresh vegetables.

No case of land scurvy appeared at the Bath United Hospital;* there the patients were never debarred the usual allowance of potatoes. At the Bath General Hospital the disease did occur. Dr. Tunstall informs me that during the scarcity of potatoes, the diet was changed; twice a week, the patients had cabbage; twice a week, rice, and peas pudding; twice a week, bread and cheese. Potatoes were entirely discontinued in the hospital for about two months, from April to June. About this time the cases occurred. The other patients in the house evinced the effects of the change of diet; had house diarrhoea, and Bath Hospital tongue; were easily effected by remedies; soon salivated; would not bear such remedies as colchicum, or iodide of potassium, and during the whole year there was an anæmic type in complaints. There was not a tendency to hæmorrhagic complaints; purpura did not appear. The class of cases to which I have already referred, in which, though there may not have been the swollen, red, and bleeding gums, there was an anæmic state, attended with muscular or lumbar pains, &c.,—were quite common. He mentions three cases of scurvy.

1st Case. A drunkard, from Bristol, came in about April, with pains in the loins and lower extremities, stains on the extremities and in the course of the tendons. This was sent as a rheumatic case. Anasarca afterwards came on, and the man died in January, 1848.

2nd Case. Admitted as rheumatic; discharged as unfit. The scurvy was discovered after his discharge, but had existed whilst in the house. This case came from the country.

3rd Case. Admitted as rheumatic; discharged as unfit. From the country.

* Continued from page 153.

* See previous note, p. 149.

These cases followed an entire deprivation of the potato before they came in, and this want was not supplied to them on coming in.

The potato, during the high price, was discontinued at the Union House, and there, as I have stated, sixty cases of scurvy occurred. Mr. Gore considers it to have been caused by the absence of potatoes and other vegetable food, except rice and bread. The supposed causes may have been in operation about three months when the morbid effects were produced; but I am bound to say that the statements of some of my informants do not bear out this view. Mr. Harries, of this city, had about six cases of land scurvy, all of them among persons whose circumstances were not very low, who had plenty of food, and were not without the potato; but whether the potato was good he could not tell. These cases were marked by spongy bleeding gums, petechiæ, vibices in the course of the tendons, and rheumatic pains. None proved fatal.

Dr. Edwards says—"Most of the diseases I treated amongst the poor were, in 1847, (especially the early part,) peculiarly anæmic in type. The same was observed here in town I learn. The cases of land scurvy I saw were confined to the poorer class. I did not meet with any among the better class of patients I was in the habit of attending. My impression at the time was, that the want of the potato specifically was neither the cause of the disease, nor of the anæmic type I observed in other diseases, but rather the almost impracticable attainment of the ordinary supply and nutritious character of food from the high price of provisions, especially vegetables, and the general want of employment which existed in the early part of 1847, and, as a consequence, physical and mental depression."

Mr. Hutchins, of Keynsham, found scurvy confined to the poor, and where there was deficiency in vegetable diet. He considers that the causes of scurvy were partly a want of ordinary diet, and partly an adynamic state of constitution, and that several months' duration of these causes produced the effects.

Mr. Perrin, of Camely, does not consider the potato failure the cause of all the mischief; but the general high price of provisions did very serious and permanent mischief, and the potato got more than its fair allowance of discredit. My brother found the cases of land scurvy in the Tisbury Union confined to the poor, and they had generally been deprived of the potato. Dr. Lindoe found the cases of land scurvy occur chiefly among the poorer classes, and he considers them to arise from a deficiency of wholesome nutritious food, owing to the privation of their usual diet—the potato. The causes may have been in operation, he thinks, three or four months, when the morbid effects were produced. He also seems to consider the crowded, ill-ventilated state of the apartments of the poor a cause of scurvy. This was my own impression, particularly in the instance I have mentioned of the man

and his wife, who were under my care. When attending them in previous illnesses I have constantly urged them to keep their apartments well aired, but without success. They seldom moved out, and had an extreme horror of catching cold. The consequence was, that their rooms were oppressive and offensive.

It is a striking circumstance, that whilst only two cases of land scurvy are reported by the Union surgeons out of the house, Mr. Gore had sixty cases in the house, and the very week that he first mentions in his report the symptoms of the disease, he also says,—“The crowded state of the sick wards naturally attracts attention; it depends mainly on the accumulation of chronic cases, and calls for additional accommodation for such cases.” And at the Bath General Hospital, where the disease did occur, the atmosphere is, probably from the vapour arising from the Bath waters which are introduced into the house, moist and unhealthy, and produces every now and then hospital diarrhœa.

It was observed to me by one of our relieving officers, that he thought one cause of the scurvy in our Union House was the alteration in the diet of the paupers on entering the house. Before entering they lived low, but were not confined to one food, and got occasionally a little gin, but in the house they had quantities of oatmeal. It may, I think, be at once allowed, that whatever tends to either mental or physical depression, will be favourable to the production of scurvy, but I question whether any cause of this description could be in itself sufficient, without the absence of a supply of organic acid in the food. There was want and illness enough last winter, and the influenza produced a peculiarly distressing effect on the general health during the winter, and indeed in its results long after it had ceased to be talked about; but though I believe there have been some cases of land scurvy this year in this neighbourhood, they have been very few. The price of the potato was high last winter, but not so high as before, and vegetables were tolerably plentiful. I should have remarked, that in the Bradford Union House it was confined to the children, and principally to those between the ages of four and twelve. The men, women, and those children who were of an age to be much in the open air, remained, with few exceptions, free from it, whilst Mr. Highmore says that not one case occurred in his practice out of the Union House; and taking fourteen consecutive cases from our Union House report, in June, I find that two of them were aged 35 and 44, whilst five were above 59, and seven below 10, years of age. Of five consecutive cases in July, one was 35, and four were above 60 years.

Those who witnessed the disease which appeared in this neighbourhood in 1847, and have referred to the account given by Dr. Shapter, of that which appeared about Exeter at the same time, will, I think, entertain

no doubt that whatever may have been the cause, they were the same; and that they answer to the disease which has been described by standard writers as sea or land scurvy. Mr. Highmore found in his cases at first almost invariably pain and heaviness in the head and weakness of the legs, many being confined to bed unable to stand before the gums became diseased. Petechial blotches, particularly on the legs, appeared in most of his severer cases, with the swollen and bleeding gums. Some of the earlier cases were ill for a very prolonged period. I observed the joints to swell, and, as I have stated, in one case to put on the usual marks of synovial inflammation. The belly became tumid. One woman applied to me to confine her, thinking she was in the family way; the citric acid cured her. Some cases terminated fatally in phthisis in a few months; and others, particularly the old, seem never to have recovered the shock, but gradually sank, though the direct symptoms may nearly entirely have disappeared. Indeed, in judging of the fatality of such a disease as land scurvy, we must not take into consideration only the cases of death, attended with its generally recognized symptoms, but must remember that where these have been overcome and the patient apparently restored to at least convalescence, other diseases have supervened, and their fatality has been determined from the shock originally given by the land scurvy. So it is in influenza: its mortality would be very inadequately estimated by the deaths occurring during its prevalence; and thus it may and does happen sometimes, that when mortality is high, the amount of prevalent disease is low, a coincidence which occurred this autumn in the district for which I am registrar and parish surgeon. In addition to the spongy bleeding gums, Mr. Perrins's cases in the advanced stage presented sloughing of the cheeks to a frightful extent. Dr. Samuel Edwards informs me that in several *post-mortem* examinations about this time, he observed extravasations of blood beneath the serous coat of the intestines and abdomen, in which such appearances were neither anticipated nor usually found. Similar to these observations is a case my friend Mr. Field has sent me an account of.

A female, pregnant with her first child, in the last month of her pregnancy, was severely afflicted with diarrhœa, and was much debilitated thereby. Labour came on but proceeded rather slowly; blood was passed per anum and she sank before delivery. On *post-mortem* examination blood was found effused under the peritoneum covering the front part of the uterus, and the corresponding portion of the abdominal parietes, in maculæ, such as are observed in purpura. The same appearances were also noted under the pleura and the pericardium covering the heart. The woman was between twenty and thirty years of age, was not an emaciated subject, and had not lived badly according to report. There was nothing wrong in the uterine cavity.

Mr. Highmore gives an interesting case of what the

sailors call bullock's liver in scurvy. He amputated the great toe just previously to the scurvy breaking out, at the centre of the metatarsal bone, in a patient aged 50. The case progressed favourably for a few days, then a fungous, livid, bleeding mass grew from the surface of the wound, becoming as large as a small orange in a month. All attempts to check its growth or set up a healing process failed. There was no altered appearance of the *gums*, but on being supplied with the lime juice, the patient lost the pain which had previously required large doses of morphia to allay it, the tumour disappeared, the part became healthy and healed.

Though the recognized cases of land scurvy may be few compared with the population, yet I think sufficient has been said to show that a scurvy diathesis did prevail during, but particularly at the beginning of, the year 1847, producing a serious effect on the general health, and giving a dangerous type to other complaints. Dr. Budd makes a remark of the deepest importance:—"Such a condition of the system,"—i.e., the scorbutic taint, "would necessarily modify the character and course of supervening acute diseases; and it is worthy of the most diligent enquiry, whether that form of scarlatina designated by the epithet *maligna*, and analogous types of other eruptive diseases, may not, in some cases, owe their peculiar aspect and character to the circumstances of a scorbutic taint already existing, when the system becomes subject to the specific poison of these several diseases." He adds in a note,—"A fact which renders this probable is, that these types prevail most during and at the close of long winters." "We may here notice the extraordinary prevalence of typhus in the severe winter of 1837-8, and the petechial character of that epidemic. Sir G. Blane has remarked, that the low spotted typhus is always most prevalent in long and severe winters. Willan states also that the malignant form of scarlatina is usually limited to the winter months." The following paragraph from Huxham's "Essay on Small-pox," may also bear on this subject:—"I have never observed either the *vegetable* or *mineral acids* of any great service in the crude crystalline pox, but I have found them highly useful in the small, black, confluent kind, with petechiæ."—*Lib. of Med.*, p. 92.

Few circumstances are more wonderful in the history of man, than the capability he has shown of bearing the severest suffering. Truthful indeed is the language of the Greek dramatist—

"Οὐκ ἔστιν οὐδὲν δεινὸν ὧδ' ἐπικλῆτος
οὐδὲ παῖθος, οὐδὲ συμφορὰ θεηλατός,
ἢς οὐκ ἂν ἀραυὶ ἀχθος ἀνθρώπου φυτῆς."

But he might have added, that not only is man capable of bearing the severest calamity, but he is even more capable of forgetting what he has borne, and of neglecting to provide against its recurrence. How pregnant is the history of land scurvy with proof of

this; though it had prevailed to such an extent, that at the end of the 16th century Sir R. Hawkins informs us that he could give an account of 10,000 mariners consumed by scurvy alone in the twenty years that he had been at sea;—that “Admiral Hosier, who set sail in the month of April 1762, with seven ships of the line, for the West Indies, buried his ships’ companies twice, and died himself of a broken heart in consequence;”—that “we are told by Dr. Lind, that during the war which terminated in 1748 in the peace of Aix la Chapelle, scurvy proved more destructive, and cut off a greater number of lives than the united efforts of the French and Spanish armies, yet it was not till 1795 that a regular supply of lemon juice was first granted to the British navy, when the mortality fell suddenly, and to a degree scarcely credible.” Between the years 1799 and 1813, the diminution of sick and of deaths in the British navy was in the proportion of four to one nearly. It was not that the means of preventing this fearful sacrifice of human life had not been long discovered, for Roussens, one of the earliest writers on scurvy, in a work published in 1564, observes, “that seamen in long voyages cure themselves of it by the use of oranges.” Sir R. Hawkins used the lemon juice in the 16th century. Lind’s “Treatise of the Scurvy,” which is still the standard work on the subject, was published in 1753, and indeed so well known was the remedy against scurvy, that Lord Heathfield, the Governor of Gibraltar, gave a family connexion of my own, Conway Heighington £500, obtained him the rank of Lieutenant in the Royal Navy, and presented him with a medal, which I have in my possession, “as a testimony of his Lordship’s high opinion of his nautical skill and bravery in getting into the relief of Gibraltar, several times during the siege, particularly on the 2nd of Feb., 1782, with a cargo of lemons for the sick of scurvy, under the heavy fire from a frigate of thirty-six guns, a zebec of eighteen, and four gunboats”—that is fifteen years before the Admiralty listened to the earnest advice of a medical man, and ordered that in future our sailors should be provided with lemon juice.

It is to be feared that we are acting in something the same manner; the potato crop has now failed three or four years, and it cannot be doubted that its failure has been one cause of the occurrence of scurvy, perhaps of other diseases, yet we have hardly attempted to find a substitute. Nay, more, it would seem from Dr. Baly’s paper, published in the *Medical Gazette*, Vol. xxxi., that though mention may not be made of its occurrence, the land scurvy is by no means unfrequent in some of our prisons, and that a diet which has been repeatedly shown to be productive of it is continued. It has been rather the fashion during the last year or two to raise an outcry against the potato. Some prophecy of Cobbett’s has

been quoted, and that which I verily believe has been the greatest friend our poor ever knew in the shape of food, is now treated with contempt, and we are bid to think of some farinaceous food in its stead, such as Indian corn. This condemnatory opinion finds support in that part of “Turner’s Chemistry,” lately published under the care of Liebig, from which I copy the following passage:—“Man being omnivorous, his mixed food contains all the constituents which are required for nutrition and respiration.” The researches of Dr. N. D. Thompson have demonstrated that the most favourable proportion between the albuminous or azotized and the saccharine or non-azotized constituents in the food of animals is, that of one part by weight of the former to seven or eight of the latter. This proportion exists naturally in the most nutritious food, such as grain, while in such food as potatoes the amount of albuminous matter is much too small. Hence potatoes alone must be regarded as very inferior in nutritive power to wheat, oats, rye, or maize, equal weights being compared.”—(“*Turner’s Chemistry*,” p. 1321.) Now, however high this authority may be, I must venture to say that my own observation some years ago, in an agricultural district, led me to believe that in reality were our poor to be confined to one kind of food, either bread or potatoes, they would prefer potatoes as the most palatable, and in the long run most nutritious, food of the two; and I do think that there is now abundance of evidence to prove that one necessary constituent of good food is an organic acid. The farinaceous seeds, as wheat, barley, oats, and rye, which are destitute of antiscorbutic property, contain no organic or vegetable acids; but “the various fruits, succulent roots and herbs, which have the property of preventing and curing scurvy, all contain, dissolved in their juices, one or more organic acids, such as the citric, tartaric, and malic acids. Sometimes these acids exist in the free state, but more generally they are combined with potash or lime, or with both these bases. Now, potatoes have been submitted to most elaborate chemical examination by Einhoff and Vauquelin, and by both these chemists they have been found to contain a vegetable acid in considerable quantity. According to Einhoff this acid is the tartaric, combined with potash and lime. According to Vauquelin it is the citric, partly in combination with those bases, and partly in the free state.”—(Dr. Baly, &c., *Medical Gazette*, Vol. xxxi., p. 703.)

In the same volume of the *Medical Gazette*, from which I extract the above, is a communication from Mr. Peppercorne, bearing testimony to “the great efficacy of sound and fresh potatoes in the prevention and cure of scorbutic disease amongst the French seamen.” They were given raw. And in a little work, “Two Years before the Mast,” which has all the appearance of being what it claims to be, an authentic narrative, there is a very interesting account of the scurvy on board an

American vessel. They fell in with a vessel which supplied them with fresh onions and potatoes, and these speedily cured them. One man, in a most deplorable condition, who could not chew the onions, had the juice of the bruised raw potatoes and onions given him. "This course soon restored his appetite and strength, and ten days after we spoke the *Solon*, so rapid was his recovery, that from lying helpless and almost hopeless in his berth, he was at the mast head furling a royal." The writer says,—“This disease is not so common now as formerly, and is attributed generally to salt provisions, want of cleanliness, the free use of grease and fat, (which is the reason of its prevalence among whalemén,) and, last of all, to laziness. It was probably from our having none but salt provisions, and from our having run very rapidly into hot weather, after having been so long in the extremest cold.” He says that medicines would have been of no use,—their's were exhausted,—“for nothing but fresh provisions, and *terra firma*, has any effect upon the scurvy.” How striking a proof is this of the amount of ignorance still prevailing on this subject, even amongst those most interested in being acquainted with it as most subject to its evils; and it shows that the neglect of merchants to provide their ships' crews with the preventive of scurvy, is not peculiar to this country where Dr. Budd has animadverted on it, but extends to America, and would really seem to arise, in some measure, incredible as it may appear, from ignorance of it.

But may not the potato derive its great value partly from another circumstance? I have long considered it a stimulating food, and that it derived its value in a great measure from this. Now, it belongs to the same natural order as the capsicum; and if the doctrine of homomorphism be true, “that plants, having similar structures, have similar properties likewise.”—*Burnett's Botany*, p. 985.) May it not possess some of the stimulating properties of the capsicum? “It is a fact,” says De Candolle, “which should never be lost sight of, that all our aliments contain a small proportion of an exciting principle, which, should it occur in a greater quantity, might become injurious, but which is necessary as a natural condiment; and that, when this stimulating principle is naturally in very small proportion, we increase it by art, or supply its place by the addition of spice”—*Burnett's Botany*.

There is a way in which the potato is used which may not have been thought of, but which I think may have much to do in preserving public health,—I mean mixed with wheaten flour in bread; I believe very few bakers omit to use it, and perhaps we may have acted unwisely in condemning this adulteration. One of the questions I put to my correspondents was, “Do you consider that the potato, as an article of diet, may be safely dispensed with?—or can you suggest any sufficient substitute? Do you consider that rice would be?” Mr. Gore says, that the impression left on his

mind was, that vegetable food is indispensable to health, and that the potato is one of the best or most convenient forms. The inmates of the Union House soon absolutely loathed rice. And his observations on these circumstances strongly confirmed a previous opinion, that rice is a very poor and inadequate article of diet. Mr. Lloyd says, that potatoes *cannot* be safely dispensed with, there is no good substitute for them; rice is a bad substitute, and produces disease of the mucous membrane of the bowels. Dr. Tunstall looks on bread and cheese as the best substitute for potatoes. Dr. Lindoe thinks that in warm climates rice might be found a useful substitute for the potato, but in England he is not aware of any vegetable that could supply its place. Mr. Hutchins does not consider that rice would be a safe substitute for the potato; thinks bread would suit the English constitution; finds peas, and grits, and salted meats, readily induce obstinate skin-disease; and carrots and parsnips do not well agree as a work-house diet without some bread. Rice, with broth or soup, and a small quantity of bread, he finds makes a very wholesome and palatable meal. Rice, even with treacle, is seldom liked; suet pudding, or bread and cheese, is always preferred. Mr. Perrin considers parsnips nearly as good as potatoes, though not near so palatable; rice will never be used, from the strong aversion the poor have to it. My brother believes that potatoes may be dispensed with, provided in their place we use some fresh succulent vegetables, as turnips, carrots, celery, cabbage, &c. In the Tisbury Union House, when the potatoes were becoming scarce, and the diet table was altered, he requested that turnips, carrots, or greens, might be given twice a-week, and potatoes once, and not a single symptom of land scurvy occurred to any inmate. He also found that those in his district who had the first symptoms of the disease, were speedily relieved from them by a vegetable diet. Rice he believes to be useless as a preventive of land scurvy, because in the Crediton Union, where it was an article of diet, several cases of land scurvy occurred. The same weight of boiled rice had been substituted for potatoes in that Union House. Mr. Shorland considers it most unadvisable that the potato should constitute, as heretofore, the general diet of the lower orders, but as an adjunct considers it preferable to rice.

(To be continued.)

CASE OF PESSARY IMPACTED WITHIN THE VAGINA FOR TWO YEARS.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

Conceiving the following case of impacted oval box-wood pessary within the vagina for the space of two years, with the singular and simple method employed

for its removal, after every other means had been resorted to, possesses a peculiar claim for publication, I will briefly give you the particulars in order that you may allow it a space in your Journal, should you, upon perusal, think it merits one.

Mrs. W., aged 60, married, but without children, about two years ago consulted a practising empiric, with symptoms of general debility and tenesmus during urination, for which he advised the use of a pessary, and prevailed upon her to allow him to introduce one, which he did with some difficulty. Her existing symptoms became subsequently much aggravated, with additional weight, heat, pain and uneasiness about the loins and vagina, with a constant dribbling away of urine. She applied again to her adviser and requested him to remove the pessary. He tried to do so by adopting different expedients, but after fruitless efforts for the space of two hours, he gave up the task and coolly assured her, she need be under no apprehension, as the pessary in a short time would rot away, without the slightest injury to her. She still consoled herself with the belief that time would remove what her adviser could not. However, her general health became more alarming, and among other practitioners, she consulted my brother, Mr. R. H. Leach, of Cowlshaw, near Oldham, who carefully examined the vagina, and found a pessary so firmly wedged therein that he could not remove it with his fingers. The other medical gentlemen whom she had consulted prior to my brother, had likewise failed to relieve her of it.

On the 1st of September, I went with my brother armed with every little invention calculated to dislodge such a foreign body from the vagina, and found the case exactly as he had described it; the woman had a care-worn countenance, was dejected in spirits, cough, disordered digestion, incontinence of urine, much emaciation of body and general debility. The sphincter ani was paralysed, most probably from long continued pressure of a large foreign body upon the muscular nerve supplying it with motion. The mucous folds of the rectum were relaxed and much congested. The pessary could be distinctly felt through the rectum in the vagina. The perineum was rigid, and though I could move the pessary within the vagina, the rigid perineum prevented an extraction. The lower orifice of the vagina was very small. The woman was now placed upon her left side and her shoulders slightly elevated; the vagina was well lubricated with lard. Two fingers of the left hand were passed into the rectum behind the pessary and traction thereby made, whilst the index finger of the right hand, which was with difficulty passed within the vagina behind the pessary, acted as a second traction. In this way the pessary could be brought to the lower part of the vagina, but the small outer orifice and rigid perineum would not allow its broad diameter to pass. Scoops, a small vectis, and various other means were then tried without success. Perforation or crushing were now the only expedients, and being distant some miles from town, we thought it probable that the best perforator would be the joiner's gimlet; and as the pessary was hollow and made of box wood, perforating with a gimlet

would most probably fracture the sphere of the pessary into different segments, which would then be readily removed by a forceps. My brother now brought the pessary as low as he could in the vagina by using traction with two fingers, introduced behind the pessary within the rectum, and steadily held it fixed against the perineum and outer orifices of the vagina with his right hand, protecting the soft parts by means of a towel, whilst I perforated the pessary with a gimlet. On the groove of the gimlet, behind the worm, passing within the hollow of the pessary, its walls fractured into three segments, the parts of which were now readily brought away with a forceps, and the operation completed.

We found that granulations had formed on the cervix uteri, which had passed within the opening usually left for a pessary tape, and were torn away with the extraction and found within the hollow of the pessary after extraction. The woman has since done very well and nearly recovered her wonted strength and spirits.

Such cases as the one I have described are rarely met with in practice. I have only heard of two, one was in the practice of Mr. Jesse, of Frodsham, who is a practical and very intelligent surgeon, and the other case was in Liverpool. I am not aware the gimlet has been tried before in such a case, but as it effectually answered my purpose, after more complicated instruments had failed, I can with confidence recommend it to the profession, as an instrument always near at hand, and calculated to realize the best wishes of the operator in such a case. Should you deem the case worthy a space in your practical Journal, you will much oblige,

Sir, your obedient servant,

JESSE LEACH.

Heywood, Lancashire,

March 10, 1849.

CASE OF PLACENTA PRÆVIA.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

If your valuable Journal has not already been inundated to too great an extent with cases of placenta prævia, I beg to submit to the notice of your readers the following case, which occurred in my practice, and was attended by my friend Mr. William Peck, of Bedford.

The case appears to me to be confirmatory of the plan first practised by Mr. Kinder Wood, of Manchester, and since, so prominently brought before the notice of the profession by the writings of Dr. Radford, of Manchester, and Professor Simpson, of Edinburgh. If you think the case worthy of insertion, I forward it to you as concisely sketched by Mr. Peck himself.

I am, Sir, your obedient servant,

T. HERBERT BARKER, M.D.

Bedford, March 14, 1849.

CASE.—On the 8th instant, I was summoned to Mrs. Rust, of Wilden, near Bedford, in labour for the third time. I found her of leucophlegmatic temperament, and naturally delicate. There had been so much hæmorrhage that the woman was nearly exhausted. On examination, I detected a globular, softish, spongy mass, immediately over the os uteri, which was flabby, and sufficiently dilated to introduce four fingers. A pain came on, and with it, a fearful gush of hæmorrhage. I was now certain that it was a case of placenta presentation. Perceiving that the woman was getting weaker, I determined immediately to remove the placenta, directing the administration of some brandy and water, and a full dose of ergot. I then introduced my hand, carefully peeling the placenta from its attachment to the uterus, removed it, divided the funis, and immediately the hæmorrhage ceased. Uterine action not coming on for some time, I repeated the secale, occasionally passing my finger around the inner surface of the os uteri, and shortly I had the pleasure of perceiving my patient rally. In about four hours from the time the placenta was removed, the fœtus was naturally expelled. The woman is doing very well. Success in these cases, in my opinion, depends upon prompt interference.

WILLIAM PECK, 14, Priory Terrace, Bedford.

P.S.—I have pursued this plan in two other cases, with the same advantage to the mothers as in the above case, and in one of the cases the child was saved; but I regret that records of the particulars were not preserved.

ON THE ADMINISTRATION OF CAMPHOR IN CHLOROFORM.

By WILLIAM DAVIES, M.D., Senior Physician to the Bath United Hospital.

In common, no doubt, with many other medical men, I have often felt it to be a matter of much regret that we do not possess a convenient mode of administering camphor in full doses. From the statement of the Messrs. Smith, of Edinburgh, and also from the comment made thereon in a late number of the Journal, I was led to suppose that the difficulty alluded to had no longer any existence, in consequence of the solubility of camphor in chloroform, and its non-precipitation on the addition of water or other ordinary vehicle. I am sorry to say, however, that the result has been by no means satisfactory. I ordered a solution to be made in the proportion of a scruple of camphor to a drachm of chloroform. The solution was perfect, and the camphor was not liberated on the addition of water; but immediately on being dropped into water, it sank to the bottom in the form of a globule, and though, by means of brisk agitation, it became diffused through the water, yet it rapidly re-accumulated at the bottom of the vessel, nor could this result be avoided except by adding so much mucilage as to render the draught unpleasantly thick. Nor is this the only difficulty, as in pouring the mixture

from the bottle into a glass, some of the camphor becomes deposited on the sides of the bottle, and also attaches itself to the glass out of which the draught has been taken, so that the patient does not get the prescribed quantity of camphor.

If any reader of this Journal knows how the difficulties here mentioned are to be overcome, he will do good service by communicating the fact in its pages.

CLINICAL ILLUSTRATIONS.

ON CORRODING ULCER OF THE UTERUS: CASE AND REMARKS.*

By EDWARD BALLARD, M.D., of Leamington, Late Senior Physician to the St. Pancras Royal General Dispensary, and Medical Tutor in University College, London.

REMARKS.

Nature of the Affection of the Uterus.—The great question with respect to *corroding ulcer of the uterus* is, whether or not it is connected with cancerous disease? That the ulcer is very obstinate in its character, very indisposed to heal, and presents a tendency to deep destruction of tissue, are points which all are agreed upon; and the fact that these characteristics are equally possessed by the ulcer from cancerous disorganization, has led to the suspicion that corroding ulcer is but one form of malignant disease. The partisans of this opinion overcome the difficulty arising from the absence of tumour, by the assumption that all trace of cancerous deposit is removed by ulceration as fast as it occurs, the removal proceeding *pari passu* with the deposition. On the other hand, it has been maintained, that analogy furnishes us in lupus, and other diseases, with examples of deeply spreading ulcers, altogether distinct from cancerous disease, and that unless distinct proof can be adduced of the presence of cancerous tissue, we must not argue respecting it from the character and position of the ulceration alone. It may be, that the case which I have recorded, will assist in throwing a little additional light upon this disputed point of pathology. I would place together four points as worthy of notice, with a view to its elucidation. First, that there was present, in my case, a considerable amount of ordinary *inflammation*. This was obvious after death, from the colour of the parts of the uterus adjacent to the ulceration, of the ecchymoses scattered though the congested portion, and from the condition of the parts of the bladder and vagina adjacent to it. Secondly, that some kind of *foreign deposit was present* near the surface of the uterine ulcer, and infiltrating the tissue which formed the base of the bladder, pressing upon the termination of the ureters, and causing their distension with the urine. Thirdly, that in this tissue were discovered, by the aid of the microscope, *cells similar to those which are met with in cancerous growths*.

* Continued from page 158.

Fourthly, that, as in Dr. Heaton's case, the *nutrition had been depraved*, from privation.

Now, I am not one by any means given to the "anticipation of nature," or disposed to generalize from individual instances, nor (to proceed still further,) am I especially anxious to insist here, or in any other case, on the discovery of "cancer-cells," as proof positive of the presence of cancer. I am not by any means so certain that what I should recognize as a cancer-cell would be equally admitted to be such by another person, or, in other words, that the cell is so peculiar, that it can belong to no other kind of growth; and hence, although I am inclined to think that the present case tends in some degree to support the view of those who hold the cancerous nature of the corroding ulcer, I am far, from believing that it was *certainly* of cancerous origin, and far less from holding the opinion that it is always so. The first and fourth of the facts to which I have above alluded deserve to be well considered; whether originally cancerous or not, had not ordinary inflammation much to do with the ulcer? Might not the ulceration have been due to this in great measure, as engrafted on, or independently of, the malignant deposit? And, lastly, had not the defective nutrition considerable influence in both Dr. Heaton's case and my own, in determining ulcerative absorption as the result of this inflammation? I believe these to have been important agencies at work in the production of the disease.

The *ulcerations and vesicular elevations on the mucous membrane of the gullet* are the only other morbid appearances to which I shall occupy the space of the Journal in alluding. In Dr. Heaton's case, ulcers, small and superficial, were found in the stomach. The œsophageal ulcerations I do not recollect having seen noticed to be preceded, as in this instance, by a vesicular sort of eruption on the membrane.

Period of Life.—In both Dr. Heaton's case and my own the patient had passed what is understood as the middle age. Dr. Heaton's patient had, we must believe, long ceased to menstruate; my patient, however, was still subject to her periodical flow, nor did it cease to appear when the more obvious symptoms of the uterine disease became manifest. The catamenia appeared in the month of August, but in that of September she was unable to distinguish between this natural discharge and the morbid one.

Outbreak of the Uterine Disease.—In Dr. Heaton's case no period is distinctly stated as that at which the uterine affection commenced. The patient is merely said to have been out of health for three or four years. Such, too, was the case in some degree with my patient. Although not ill enough for her ailments to attract much of her attention, or to prevent her following her customary avocations, or even to be an obstacle to active exercise, she had plainly been falling off in her health for some time, some symptoms of uterine disease, with hæmorrhoidal discharge, having from time to time presented themselves. Her husband also assured me after her death, that she had been subject to passing blood with her urine for some months before she suffered any pain. The more obvious symptoms of her complaint however, and what most persons

would have designated as its commencement, were attributed by herself to over exertion. Much serious disease may be advancing in the frame with but little token being afforded, and hence little suspicion being aroused of its existence, when all at once subsequent to, and no doubt under the superadded influence of, some otherwise trifling occurrence, the system gives way, the latent affection bursts into light, and runs a rapid course to a fatal termination. Clinical observers know this well.

The precise *duration* of the disease of the uterus is difficult to determine. Probably it had existed in a latent form for some months prior to its manifest outbreak, possibly for two or three years, or as long as the patient had been subject to vaginal discharges. If so, there will be in its chronic progress a similarity to Dr. Heaton's case.

Symptoms.—The symptoms of the uterine disease were very distinct in the two cases. In Dr. Heaton's, the repeated floodings led to the suspicion of uterine ulceration, but the pain and hypogastric tenderness were trifling in amount. In that which I have reported there had been no flooding whatever, the uterus having only previously displayed disorder of its function in the several miscarriages which had taken place. The pain in the loins, sacrum, thighs, and groins, due, no doubt, in great measure, to the renal affection, constituted here the most remarkable symptom, and was especially induced by the passage of feces through the rectum; a point of interest too, connected with this pain was its plainly *rheumatic character*. By a superficial observer, it would have been no difficult matter to have overlooked completely the disease in the womb. The patient, a weakly woman, was exposed to cold and wet. Some days after, in consequence, perhaps, of over walking, she was attacked with pain in the loins and thighs, (the vomiting might have arisen from the ale she had taken having disagreed with her.) The pains continued for some weeks, increased by warmth, aggravated by motion, always worse at night, relieved by moderate exercise, and always more complained of when a change took place in the weather. Until the futility of anti-rheumatic remedies had been discovered, no enquiry might have been instituted into the condition of the uterine and urinary system, and many women are slow in mentioning them spontaneously. Such an error was very possible in the hurry of dispensary practice, and, perhaps, under such circumstances, might not have been quite unpardonable. The masked character of the symptoms in this case only impresses upon the practitioner more strenuously than ever, the great importance of the practical rule of enquiring, whatever the apparent disease, into the condition of every organ of the body. The *discharge* from the vagina was, on every occasion that I had an opportunity of examining it, tinged with the colouring matter of the blood; still the patient described it as "like water," and so did Dr. Heaton's. The patient's description of a vaginal discharge, I have found, is never to be relied on. "Thick" and "watery" are the only terms employed to designate its character, and the practitioner is pretty sure to be led away if he depends on anything

but his own eye-sight in satisfying himself on a point like this. *Vomiting*, with *constipated bowels*, and *indurated faces*, were remarkably present in both cases.

Before passing to the observations I have to make on the diagnosis of the disease, I wish to offer a few remarks on the *vaginal examination*, and this more by way of caution than anything else. I suppose that no one in the present day would proceed to treat a case of severe, or even apparently trifling, uterine disease, without physical evidence, if he could obtain it, both to the finger, and, by the aid of the speculum, to the eye, of the actual condition of the organ. Some women are so foolish as obstinately to refuse the practitioner this means of investigation, but when its importance is properly represented, and its necessity firmly insisted on, I have rarely failed to obtain it. But what I wish to refer to is, the fact noticed in the report of the *post-mortem* examination, that on passing the finger into the vagina, so as to feel the ulcer of the cervix; it passed through the thin membrane left by the ulceration, and entered the cavity of the peritoneum. I need not say much here respecting the extent of the ulceration in this form of disease; enough is reported upon that head, and scarcely requires repetition. But the necessity of great caution under these circumstances in making vaginal examinations, cannot be repeated too often. The accident which occurred after death might have taken place during life. Corroding ulcer of the cervix uteri is not so far from the peritoneum, especially when it begins to attack the body of the organ, but that a trifling pressure of the finger, or a little rudeness in the mode of examination, may be fatal to the patient. A distinguished professor once informed me that he feared that in a case of corroding ulcer, he had once himself, unavoidably, hastened in this way the fatal result. A further caution may be given with respect to the kind of speculum to be employed. In many cases of uterine disease there is an advantage, in my opinion, in the use (at a first examination,) of a cylindrical speculum, avoiding those which act by dilatation, until it has been ascertained that the dilatation can be productive of no injury. In corroding ulcer of the uterus especially this precaution is of value, as the same accident may happen as from digital examination.

Diagnosis.—I did not recognise this case during life as one of corroding ulcer; but as one of ulcerated cancer of the cervix uteri; nor, as I said above, am I certain that the diagnosis was incorrect. The absence of lancinating pain might be readily accounted for by the absence of the indurated tumour, which is known to be its cause. When the patient first presented herself for treatment, I was struck with her remarkable sallowness and pallidity, and in the lack of any hæmorrhage to account for it, I was led to institute an enquiry into the condition of the uterine system. The existence of the vaginal discharge, of an extensive excavation of the cervix uteri, with a hardened and irregular edge, taken in conjunction with the sallowness and pallidity to be accounted for in no other way, led me to conclude that, although no obvious tumour was discoverable, I had to treat an ulcerated cancer of the

cervix uteri. The occurrence in the progress of the case of large cells, like those of cancer, in the urine, and at length of the cancerous odour in the vaginal discharges and in the urine, with increasing weakness and emaciation, confirmed the opinion which I had formed of its nature.

I have studiously confined the foregoing observations to the principal disease, and would only further remark, in respect to its complication, that during the latter days of the patient's life, the pains which had marked the uterine affection were scarcely complained of at all, being obscured by the overwhelming torture arising from the vaginal ulceration and the vesico-vaginal communication, every gush of urine or discharge eliciting the most distressing cries.

The treatment under the view I took of the case, could only be directed to palliation, and an endeavour to support the system, and improve the digestive functions. With this view gentian and sulphate of bebeerine were administered to her when she first came under treatment, and suppositories of opium and soap, and afterwards of belladonna, were employed, till the condition of the bowels forbade their further use. In the latter periods of the complaint, local pains were sought to be relieved by the application once or twice of a few leeches, by turpentine fomentations to the abdomen, warm water fomentations to the vulva, muriate of morphia, &c.

Leamington, February 11, 1849.

PROVINCIAL
Medical & Surgical Journal.

WEDNESDAY, APRIL 4, 1849.

We have on former occasions contended for the right of medical men to remuneration on giving information to Life-Assurance Offices, by which the assurance of lives may be more safely and advantageously effected. While admitting this right, the offices have very generally urged that the party insuring his life should pay the fee to his own medical man, the offices on their part being responsible to their own referees. This may have an equitable appearance in theory, but is not found equally feasible in practice. The insurer very commonly objects to the paying of this fee to his own medical adviser, and expects that the necessary questions will be at once answered by him as are those by the non-professional friend to whom reference is also made; while, on the other hand, the information required from the medical attendant may be, and often is, of that character which, while it is of essential importance to the office to know, at the same time proves to the disadvantage of

the party insuring, and consequently places the medical man in an unpleasant position with his former patient.

It is unnecessary to go through the arguments which have been so often brought forward on this question. However just the claim of the medical man, it has been hitherto disregarded, and he has been exposed to various injurious consequences, as he may have acted conscientiously towards the office on the one hand, or refused to give the required information on the other.

Through the exertions which have been made by the medical press, and by certain Associations of medical men, and in particular by the Manchester Medico-Ethical Association, some of the offices have at length been brought to see the question in a more equitable light, and looking to the influence which medical men cannot but have with their patients, we are inclined to hope that the final adjustment of the matter now remains in their own hands. Whenever a difficulty occurs in future respecting the payment of the fee to the medical attendant, it is easy to inform the party proposing to insure, that, although one office may raise an objection on this point, there are others of equal respectability which will be ready to effect the assurance, on terms equitable to all parties.

Several Life Assurance Offices have now adopted the principle of remunerating medical men for their reports, and we believe that we cannot do better towards carrying out this principle than by here subjoining a list of them:—

Britannia, 1, Princess Street, Bank, London.

Professional, 76, Cheapside.

British Mutual, 17, New Bridge Street, Blackfriars. Yorkshire, York.

Church of England, Lothbury.

National Mercantile, Poultry, Mansion House.

Solicitors' and General, 57, Chancery Lane.

Westminster and General, 27, King Street, Covent Garden.

General Benefit, 4, Farringdon Street.

English Widow's Fund, 67, Fleet Street.

Legal and Commercial, 73, Cheapside.

Medical, Invalid, and General, 25, Pall Mall.

Engineers, Masonic, and Universal, 346, Strand.

Star, 44, Moorgate Street.

Prudential Mutual Assurance 14, Chatham Place, New Bridge Street, Blackfriars.

Review.

Practical Observations on certain Diseases of the Chest, and on the Principles of Auscultation. By PEYTON BLAKISTON, M.D., F.R.S., Fellow of the Royal College of Physicians, &c. &c. London. 1848. 8vo, pp. 368.

The author of this very useful and practical work has long been favourably known to the profession by his researches upon some forms of valvular disease of the heart. His object in the present treatise is to bring together the results of his experience in hospital and private practice upon several other important affections of the heart and chest. A brief introduction to the principles and practice of auscultation is prefixed, together with a series of short propositions, illustrated with appropriate explanations and diagrams on the physical properties of sound. This work does not profess to be a systematic one, but contains much valuable information on the diseases of which it treats. The principal of these are—thoracic aneurism; chronic heart-disease generally; pleurisy; pneumonia; and phthisis pulmonalis. The greater, and in our opinion the most valuable, portion is that devoted to the consideration of diseases of the heart, many of the cases of which are of great interest; these, however, it is obvious, we are precluded by our limited space from referring at any length; we prefer, therefore, extracting some general remarks on the treatment, which, with certain modification, will, we believe, be found applicable to most heart affections.

"A certain number of cases of valvular disease, hypertrophy, and dilatation, with attenuation," observes Dr. Blakiston, "result from inflammatory attacks. Some of these, as acute pericarditis, are well marked, and therefore are generally recognised. If such cases were treated on the plan detailed in the chapter on pleuritis, with mercurial frictions and leeching, rather than by copious venesection, I cannot but think that the consequences would be in general less serious than they usually are, that the heart would less frequently adhere to the pericardium, and that hypertrophy, dilatation, and valvular disease would be less common." And again—"Dr. Hope has pointed out the injurious tendency of such extensive venesection, from its inducing a state of anæmia with its concomitant evils. But if the views in the tenth chapter of this work are correct, there is another very powerful reason against this treatment; for, in proportion as the power of the muscular walls is diminished by it, so is the tendency to dilatation and tricuspid regurgitation increased, whereby congestion of the general venous circulation is produced. With these dangers before us, it is impossible to carry the system of depletion to any great extent. We must be content to relieve the tension of the vessels, when it seems considerable, by small bleedings, or by the application of cupping-glasses and leeches to the precordial region. This plan will often succeed more effectually in quieting the action of

the heart than more copious blood-letting, which is often followed by strong reaction. At the same time sedatives and rest materially assist; in fact, it is seldom necessary to abstract blood at all, if the patient be kept free from mental or bodily disturbance."

"If, now, the action of the heart be enfeebled, it matters not whether this arise from attenuation or from a fatty and flabby state of the walls of the ventricles; in either case a tonic and sedative treatment is clearly indicated. This will in most cases be best carried out by a generous diet, combined with mental repose, and such an amount of exercise as shall invigorate the system without inducing fatigue or hurrying the circulation. The sesquichloride of iron, with hyoscyamus, is a valuable remedy in such cases."

Dr. Blakiston carefully points out the variations in the treatment to be made according to the varying nature of the organic change, state of the circulation, &c.; but the general principle of treatment applicable to very many forms of chronic heart disease is as we have stated, and none will be found more effective than a carefully regulated diet, together with the exhibition of iron, in combination with sedatives, as pointed out by Dr. Richard Chambers, (late of Colchester, now of London,) in this Journal.

Though not connected in any way with the preceding subject, it may interest our readers to hear that Dr. Blakiston has witnessed "very beneficial results" from the use of the cod-liver oil in pulmonary phthisis. The recent valuable paper on the use of this medicine in consumption, by Dr. Charles J. B. Williams, published in the first number of the *London Journal of Medicine*, January, 1849, ought to be consulted by every medical practitioner, as we cannot but think, if similar results are found to follow the employment of the oil in the hands of others as have been observed by Dr. Williams, it will prove a most valuable means in the treatment of this devastating disease. To give a fair trial, however, of the remedy, Dr. Williams's directions as to its mode of exhibition and the other parts of the treatment should, in the first instance at least, be implicitly followed.

Proceedings of Societies.

BIRMINGHAM PATHOLOGICAL SOCIETY.

October 5th, 1848.

Dr. FLETCHER in the Chair.

HÆMOPTYSIS SUDDENLY FATAL; ITS SOURCE NOT DISCOVERED.

Dr. Mackay related the following case:—

A married woman, aged 28, delicate looking, and of spare figure; while suffering from cough and slight pain in the chest was suddenly seized with hæmoptysis, which, from the quantity and rapidity of the discharge alarmed her much. The violence of the attack continued for about an hour, during which she expectorated fully half a pint. The usual remedies, including

venesection, were resorted to. For a few days the expectoration was tinged with blood, but her condition appeared to promise a gradual recovery, when ten days from the first attack and while quietly lying in bed, another attack of hæmoptysis came on, and she expired in two or three minutes, apparently from suffocation, after bringing up a considerable quantity of blood, which was discharged from the nose as well as from the mouth.

The chest and abdomen were examined. In the former the apex of the left lung adhered to the costal pleura over a space as large as a shilling, and corresponding to this a cavity, large enough to hold a pigeon's egg, was detected on incising the lung. The cavity was empty, and neither around it nor elsewhere was any tubercular matter found. The lower lobes of both lungs were gorged with blood, but nothing like apoplectic spots could be seen. Stomach full of blood; abdominal organs healthy.

Mr. Alfred Baker presented a fine specimen of osteo-sarcoma of the left tibia; the limb was removed by amputation. The patient did well.

(July 6th 1848.)

Dr. Percy presented drawings to illustrate the morbid appearances in the following case:—

TUBERCULAR MATTER IN THE CEREBELLUM; TUBERCLES STUDDING THE PERITONEUM, VISCERAL, AND PARIETAL; TUBERCULAR MATTER IN THE FALLOPIAN TUBES AND UTERUS; NO TRACE OF TUBERCLES IN THE LUNGS.

Mary Ann Hands, aged 18, coach-lace weaver, admitted into the Queen's Hospital, March 6th, 1845. Occupation—confining; aspect pallid. She was apparently quite well until the last two months, during which time menstruation, which commenced two years ago, has not occurred. She now complains of pain in the head, compared to a weight shifting from one part to another, but generally seated at the occiput; no globus; appetite tolerable; "food lies rather heavy;" flatus; tongue coated; bowels generally confined; pulse languid; thirst; urine copious and pale.

R. Inf. Calumbæ, oz. vj.; Dec. Aloes, Co., oz. ij. M. Sumat oz. j. ter die. Hora somni sumat Pil. Hydrarg. gr. iij., cum Extr. Coloc. Co., gr. x.

Dry cupping to the nape; ordinary diet; to walk out frequently.

March 15th. Pain at the occiput much relieved: immediate relief from dry cupping, continuing about three hours afterwards; complains of sharp pain in the temples, occurring frequently and lasting about ten minutes; appetite good; bowels regular. Cont. mist. et habeat mist. purg. oz. iv.

22nd. Headache still relieved by dry cupping; dimness of sight previously complained of continues; appears stupid and inactive.

R. Ferri Sulph., gr. ij.; Extr. Aloes, Pil. Rhei Co., utrque, gr. iss. Fiat pilula, ter die sumend. Olei Ricini, oz. ss., cras mane sumend. Dry cupping to be repeated.

24th. I learned to my surprise, that the patient died

suddenly yesterday. At my visit on the 19th, I found her in bed in a somewhat excited condition, which I was inclined to attribute to the fact of her having passed a stool involuntarily. I was not apprised at the time of the occurrence of anything like a fit; the nurse merely said that the patient had had an unfortunate accident, which she attributed to a purgative medicine taken that morning. To-day, however, on minutely interrogating the nurse, I find, that, agreeably to my direction, the patient had been walking out in the garden before my visit at eleven; that she came in about half-past nine, sat down on the bed-side and complained of feeling very ill; she immediately afterwards reeled and fell on the floor, and during that time passed a stool involuntarily. Ten minutes elapsed before she was able to speak, when she asked for water; half an hour afterwards she appeared to be well again, and in the following afternoon was *very lively*. During the last three days she had seemed decidedly better than ever since her admission; and when I saw her last she made no particular complaint, although from her appearance and dimness of vision, I entertained a suspicion of the possibility of cerebral mischief. At ten minutes past eleven, on the 23rd, after conversing as usual, she was again suddenly seized with reeling; she struggled and became "black in the face." She was immediately laid on the bed and expired; again an offensive stool was involuntarily passed. She had vomited at half-past nine, after breakfast. She had never made the slightest complaint of abdominal pain. There had been neither numbness nor loss of power in any part. The hearing was as good on one side as the other. I had remarked that the pupils were generally large; but at my last visit I observed that they were less than natural.

On the 28th I saw her aunt, with whom she lived, and received the following information:—During the first six years of her life she was a delicate child, but ever since, until Christmas last, she had enjoyed good health. She had a severe attack of scarlatina, when about six years of age. The illness commenced with severe *frontal* headache, which she said "was not like a headache," and which she relieved by tying a handkerchief round her head. She became dull, stupid, and inactive, and her aunt "feared she would lose her senses." About a month ago, between seven and eight at night, she rose suddenly from her chair, put out her hands, and called to her aunt "to come and hold her." She was put down upon her chair, she had slight convulsive twittings of hands and feet, but to a greater extent in the latter than the former; her countenance was pale and her eyes were closed, and "she appeared almost dead." There was no convulsion of face. She continued quite insensible in this condition for about a quarter of an hour, when after the application of a piece of singed rag to the nostrils, she recovered as though from a swoon; she did not pass a stool during the attack. About a week afterwards, she remarked to her aunt, that the "pain was gone to the back of her head, and was confined to a space about as large as a five-shilling piece, and it appears to her as though there was something alive in it." She had been subject to a discharge from each ear. Her aunt

never heard her complain of abdominal pain. From the commencement of her illness she has occasionally vomited her food; but of late the vomiting had been less frequent. She had neither brother nor sister alive. She lost a sister ten years ago by measles. Her mother died seven years ago, at 35, "rather suddenly." Her father is still alive. Before she came into the Hospital, she had been under the care of Dr. Sandys at the Dispensary.

Autopsy at four p.m. Present—Dr. Fletcher, and Mr. Turner.

Head first examined. On removing the *dura-mater* we were struck with the *flattened* appearance of the cerebral surface, as though the skull had been too small for the brain; the arachnoid seemed to be drier than usual; there was some congestion of the vessels of the *pia-mater*. The brain was sliced off *in situ*; the bloody points were more numerous and conspicuous, and the blood was evidently more liquid than usual; the lateral ventricles were fully distended with limpid liquid. We remarked nothing abnormal in other respects. The choroid plexus appeared quite healthy. I then removed the brain, and proceeded to examine it from the base. There was no sign of excessive congestion on the surface in any part. I sliced it up in every direction, but without discovering any evidence of disease until we reached the cerebellum, when we found distinct deposit of tubercular matter, of about the size of a walnut, situated posteriorly immediately beneath the surface, near the line of junction of the lobes, but principally on the left lobe. There was also a cretaceous tubercle, of the size of a large pea, on the right of the collection of tubercular matter, which was of tolerably firm consistency, and which, except into two or three internal points, had not softened. The presence of the matter was instantly and distinctly recognized by touching the external surface of the cerebellum. *Chest*: Old adhesions on the right side. We examined the lungs most carefully in every part by slicing, but without discovering a trace of tubercle. Knowing this to be the exception to Louis's law, we were the more minute and careful in our examination; frothy red serum exuded copiously by section. The heart was small, but in every respect normal. *Abdomen*: No peritoneal effusion. Every part of the peritoneum, (visceral as well as parietal,) was thickly studded with translucent tubercles, of a greyish colour, and of the size of an ordinary pin's head. The omentum, which was similarly affected, extended to the pelvic cavity, and adhered to the peritoneum lining the lower part of the abdominal parietes anteriorly. *Liver*: Patches of old adhesion here and there to diaphragmatic surface; structure appeared to be healthy. Gall-bladder moderately distended with bile, of ordinary consistence and colour. No gall-stones. *Spleen*: Tubercular points, of the kind above described, scattered over the surface, but no tubercular matter in the interior. The surface obtained by section attracted our attention, the fibrous portions being more conspicuous than usual. *Pancreas*: No morbid appearance. *Kidneys* healthy in structure, but congested. *Uterus*: Fallopian tubes considerably enlarged, and containing true yellow tubercular matter. The uterus

was cut open vertically; the internal surface presented a striking appearance. On careful examination, and scraping cautiously with the scalpel, we found it to arise from true tubercular degeneration of the mucous membrane itself. We remarked nothing unusual in the ovaries. The peritoneal covering of the uterus was studded with minute tubercles. *Stomach and Intestines*: The vessels appeared generally much congested; every portion of peritoneal covering was studded with minute tubercles. One portion of the ileum was somewhat contracted by a strip of membrane passing from it to an adjacent piece of intestine. The whole intestinal tract was laid open, but we remarked nothing abnormal in the condition of the mucous membrane.

Observations.—1. The history of this case is deserving of special attention. No symptom at first came to my knowledge, to indicate the existence of serious disease, for I had heard nothing of the fit with which the patient had been seized previously to her admission into the hospital. Having been engaged in a sedentary and confining occupation, she had not menstruated for two months, and in such circumstances nothing would be less likely to excite surprise than the occurrence of cephalalgia of one kind or another. The pain was chiefly referred to the occiput, although it was not exclusively confined to that part. Some days after her admission, I noticed particularly her complaint of dimness of vision. There were only three positive symptoms present to point to the disease of the cerebellum,—viz., *pain at the occiput, dimness of vision, and the convulsive attack*; and as I have before remarked, I was ignorant of the last before her decease. There was no ground for supposing the presence of tubercular matter in the lungs, and hence on the authority of Louis, and of observers generally, there was strong negative evidence against the presence of tubercular matter in the brain. Louis, at one time, it will be remembered, stated it to be a *general law*, that “after the age of fifteen, tubercles do not present themselves in any organ without being likewise seated in the lungs.” (Transl. by Sydenham Soc., p. 153.) But since the first promulgation of that law, several exceptions have been published, of which Louis himself alluded to three, in his second edition, and the present case is an addition to these exceptions; still the law must be received as *general*, though not *universal*.

Of the numerous published cases of the occurrence of tubercular matter in the cerebellum, I may, with propriety, introduce the following, recorded by Abercrombie, (“Diseases of the Brain,” 3rd ed., p. 168,) on account of its similarity in many respects to the case of Hands.

“A gentleman, aged 34, in the year 1825 first began to be affected with occasional attacks of headache, which were usually accompanied by vertigo and dimness of sight. In 1827 the pain became more severe, and was distinctly referred to the occiput and superior part of the neck. He had generally remissions of it through the day, and aggravations in the evening. In the spring of 1828 the symptoms increased in severity, but he received

considerable relief from blistering. In the summer he went to the country, where his general health was much improved, and his headache greatly mitigated. He continued in this improved state till May 1829, when the attacks of headache were again aggravated, accompanied by giddiness, and on one occasion he fell from his chair. In October of the same year he began to be affected by a most distressing sensation of throbbing, referred to the back part of the head; and he was also affected with vomiting, which continued without intermission for three weeks. The paroxysms of headache were now aggravated to an intense degree of severity; they occurred chiefly in the evening, from six o'clock till midnight, but also at other times in the day. During the more severe attacks his face was flushed, the vessels of the temples were remarkably distended, and he lay in a state nearly of unconsciousness, unable to speak, and with his hands and arms spasmodically contracted. He still had occasional vomiting, and intense acidity of the stomach, and several times complained of double vision. The pulse was generally natural. His situation was now considered as nearly hopeless, and no relief was obtained from any remedies; but after five or six weeks of intense suffering, the symptoms gradually remitted, and during several weeks in December and January, he continued almost free from headache; he was able to walk out, and his general health was greatly improved. In February, 1830, the symptoms again increased, but the pain was now chiefly complained of above the eyes; the remissions also were more complete, and upon the whole his sufferings were less severe than during the attack in November. In March his complaints again subsided, and he was able to take a good deal of exercise in the open air, and to attend a good deal to his business. He had still occasional attacks of headache, but they were not severe, and his condition was considered as much more favourable than it had been for a long time. In the middle of April the paroxysms of headache became more severe, but by no means in the degree in which they had occurred on former occasions. He was not confined, and no degree of apprehension was excited until the 24th, when, in one of those paroxysms, he suddenly expired.

“*Inspection*.—The ventricles of the brain contained from three to four ounces of limpid fluid, but the surrounding parts were entirely healthy. Imbedded in the substance of the left lobe of the cerebellum there was a tubercular mass, the shape and size of a very small walnut; externally it was firm, and presented the usual appearances of the scrofulous tubercle, internally it was softened, with the common appearance of unhealthy scrofulous suppuration. The substance of the cerebellum around it was entirely healthy. No other appearance of disease was discovered in the head, and the other viscera were sound.”

2. The presence of tubercular matter in the uterus and Fallopian tubes in this case is extremely interesting, on account of the comparative rarity, and upon this subject I may appropriately cite the observations of the great observer in phthisis, M. Louis, (“Transl. of Louis by Sydenham Society,” p. 119.) “Since the publication of the first edition of this work I have not met with tuberculous disease of the uterus more frequently than before;

out of two hundred phthisical females and upwards, three only furnished examples of that condition. No doubt, indeed, can be entertained of its rarity, for, as has been observed by M. Reynaud, in an excellent "Essay on Tubercles in the Uterus," Bayle makes no mention in his "Researches on Pulmonary Phthisis," of an anatomical alteration of the uterus, referable to tuberculous degeneration of the organ. No example of the kind is to be found in the "Clinique" of M. Andral.* Laennec is silent on the point. And M. Reynaud himself, during a sojourn of six years in the Paris hospitals, (five of these in La Charité,) employed as he was in opening a great number of bodies, met but once with the lesion in question. In the year 1830, while engaged in clinical observations at the Hospital of La Pitié, the same inquirer met with two additional cases of tuberculous affection of the uterus. The subject of one of these cases, aged 39, menstruated first at the age of twelve, and continued to do so in a regular manner until 1829, having had some favourable confinements. She died after nine months' illness. On examination after death, softened tuberculous matter, mixed with mucus, which flowed forth upon slight pressure of the neck of the uterus, was found in the interior of the vagina, together with a multitude of ulcerations, varying in size from that of a lentil to that of a centine, of more or less irregular shape, with a red fundus, and much more numerous at the posterior than lateral aspects of the passage; there were none of them anteriorly. The uterus was a little more than three inches and seven lines (9 centimetres), long, and the anterior lip of the neck somewhat swollen; the interior of this part exhibited a yellowish colour, and contained a stratum of tuberculous matter, the most superficial part of which could be easily rubbed away, while the most deeply-seated, one line (2 millimetres), thick, was combined with the substance of the uterus, irregular in outline, and divided by a number of broken furrows, which gave it something of a mammillated aspect. Besides this, the tissue of the uterus sent into the substance of this tuberculous stratum certain processes, from which sprang a multitude of delicate vegetations, capped as it were with tuberculous matter. A tubercle, of the size of an ordinary pea, was found in the substance of the body of the uterus, and underneath the tuberculous stratum: its tissue was somewhat greyish, and slightly transparent, so that it might be made a question whether this state had not, as in the lung, preceded the yellow and opaque. The Fallopian tubes, too, were filled with tuberculous matter, and their calibre increased to more than five times the natural amount; their internal surface even exhibited tuberculous matter."

Abercrombie also ("Op. cit.," pp. 164, 165,) relates the case of a young lady, aged 18, in which tubercular matter was found in the right hemisphere of the brain,

in the cerebellum, and in the lungs. "There was" also "much disease of the uterus and ovaria, which were considerably enlarged, and the Fallopian tubes, in particular, were very much enlarged, and distended with a soft cheesy matter of a yellow colour."

Dr. Carswell appears not unfrequently to have met with tubercular matter in considerable quantity in the uterus and Fallopian tubes. He remarks that he has "found the cavities of both filled with it, and the Fallopian tubes distended to the size of the finger or thumb."—"Cyclop. Pract. Med.," vol. iv., p. 258.

In the *Medical Gazette*, July 4th, 1845, vol. xxxvi., p. 40, is an interesting statistical paper "On the Presence of Tubercles in different Organs," translated from the *Gazette Médicale*, January, 1845. The facts were obtained by M. Cless, of Stuttgart, from the examination of upwards of 160 bodies affected with tubercular disease. "In twenty-six women who died of pulmonary phthisis, tubercles were found in the genital organs; once in the walls of the uterus; once in the peritoneal covering; twice on the internal surface of the uterus; once the whole substance of the uterus was converted into tuberculous matter; twice the ovaries were the seat of tubercles; and four times the Fallopian tubes were filled with tubercular substance. The tubercles in the genital organs were always secondary to the general tubercularization, especially occurring where the abdominal viscera were the seat of disease."

Dr. Watts, of Manchester, has also an interesting case of the existence of tubercular matter in the Fallopian tubes of an unmarried female, aged 24, who after having been long subject to menorrhagia, ultimately died of phthisis. "The uterus and ovaries were healthy, but the Fallopian tubes were crammed full of tubercular matter, and distended so as to equal the little finger in size. The coats of the tubes were considerably thickened, but not remarkably congested. Both lungs were infiltrated with tubercle in every lobe, and in the superior lobe of each were numerous cavities. No other organ was diseased." *Medical Gazette*, Dec. 24, 1847, vol. xi., p. 1115.

3. It is worthy of remark, that notwithstanding the copious diffusion of minute tubercles over the whole peritoneal surface, yet there was neither abdominal pain nor tenderness, nor other symptoms to indicate this diseased condition. However, these milary translucent granulations were only in their incipient state.

Foreign Department.

ABSTRACT OF THE PROCEEDINGS OF THE ACADEMIE DE MEDECINE, PARIS.

EXTRA-UTERINE PREGNANCY: GASTROTOMY.

Subsequent to our last report, M. Tueffard presented the details of a case of *extra-uterine pregnancy cured by gastrotomy*. The patient, a little, thin but healthy woman, aged 40, previous to the commencement of her present illness, had been pregnant five times. Of these, the first four pregnancies ended

* I do not, however, find this statement confirmed by reference to the "Clinique Médicale" of M. Andral, who thus writes, ("Cl. Med. Transl. by Dr. Spillan," 1836, p. 542,) "We have found these tubercles in the tissue of the uterus, in the ovaries, and even in the substance of the Fallopian tubes; but these cases are uncommon, and the genital organs of both sexes must also be placed among those parts which, in phthisical patients, become least generally the seat of tuberculous degeneration."—J. P.

in premature labour at seven months, the fifth arrived at full term. The extra-uterine was the sixth pregnancy. The foetal movements were very perceptible up to the sixth month, when after exertion the patient felt the child suddenly start up towards the left hypochondrium, and then fall back again in the iliac region of the same side. She had at the same time violent abdominal pain and considerable hæmorrhage. From this time the foetus ceased to move, and the body diminished in size. Her symptoms afterwards were frequent and copious hæmorrhages of periodical occurrence, in the intervals excessive abdominal pain. When seen by the author these symptoms had continued for six months. He discovered a tumour above the right groin, in which it was easy to perceive the form of the foetus. The os uteri was healthy and closed, the cervix of its natural size, and the whole organ was moveable. The patient being very anxious for an operation, after the inhalation of æther the author made an incision over the tumour, in a direction parallel to the linea alba. After dividing the skin, muscles, and peritoneum, he came upon a whitish membrane, forming a cyst and containing a matter very similar to adipocire; below this was another cyst which contained the limbs and trunk of a foetus, the head and upper extremities having escaped into the general cavity of the peritoneum, to which they had contracted firm adhesions. Further examination shewed that the fundus of the uterus was destroyed, the cyst containing adipocire being closely adherent to, and forming one cavity with the uterus; the cysts were removed and the abdominal incision closed by interrupted suture. As the vagina communicated directly with the peritoneal cavity, it was not necessary to insert a tent into the lower part of the incision, the discharges being enabled to draw off *per vias naturales*. The subject of this extraordinary case is said to have perfectly recovered.

The Academy was subsequently occupied with a renewed discussion on the fatal cases of chloroform inhalation, but nothing transpired worthy of further notice.

ABSTRACT OF THE PROCEEDINGS OF THE ACADEMIE DES SCIENCES, PARIS.

PERIOD OF INCUBATION OF ANIMAL POISONS.

M. Renault detailed some experiments instituted for the purpose of determining the period of incubation of certain animal poisons,—as glanders, and the sheep-pox? (*virus claveloux*.) The result demonstrated that in the former, the lapse of an hour was sufficient to prevent all chance of benefit from excision or cauterization; and in the sheep, cauterization within ten minutes of presentation proved equally unsuccessful.

LOCAL ANÆSTHESIA.

M. Roux read a memoir on local anæsthesia, chiefly by means of chloroform. He states that the local effects of this agent vary accordingly as the patient in

an operation had or had not been submitted to inhalation. In the latter case the local application of chloroform to a wound was followed at first by intense pain and heat, which was, however, soon replaced by cessation and a calm which lasted for many hours. If, on the other hand the patient had inhaled chloroform during the operation, he did not feel the local application at all, and many were thus enabled to avoid the pain which usually follows surgical operations. M. Roux has also used chloroform with advantage as an injection for the cure of hydrocele.

ON

LIFE INSURANCE AMONG MEDICAL MEN: PROVIDENT SOCIETIES: ANNUITY & ENDOWMENT INSTITUTIONS: AND THE BENEVOLENT FUND.

By WILLIAM NEWNHAM, Esq., Farnham.

As an abstract question, there are, probably, few who would have the hardihood to doubt the existence of much real distress amongst our professional brethren and their families, nor the paramount duty of endeavouring, on the one hand, to relieve that distress, and, on the other, to prevent its occurrence. But how comes it that, as a practical question, this duty is not regarded as imperative upon each individual, according to the means which he possesses? and that almost every one differs from his neighbour, as to the best means of accomplishing the object in view?

For the sake of our common humanity, it is to be hoped that the former arises in a great measure from not being acquainted with the extent of the evil, and from a forgetfulness of the necessity for doing *at once* that which may be done at any time, and which is consequently unhappily adjourned from day to day, till the day of thought and action has passed by. Yet is it to be remembered, that ignorance and forgetfulness are *both criminal*; they are not excuses for a neglect of duty; there is no excuse for not possessing knowledge which may easily be obtained; and to adjourn the action grounded upon such knowledge till to-morrow, is only the intense folly, or worse than folly, of him who postpones the saving of a starving fellow-creature till to-morrow,—till death has closed upon his miseries, and for ever shrouded to-morrow from his sight.

There may be a difference of opinion as to the mode of preventing this distress, or of relieving it when present; but it is a remarkable fact, that no one of the different plans which have been proposed for these purposes, is adequately supported. And it is an equally remarkable fact, that a profession which is celebrated for the amount of time, and energy, and cash which it gives away unrequited, amongst the poor, and others who can render no recompense, should, as a profession, be so backward in relieving the necessities of its own brotherhood. Far be it from me to suppose that this backwardness should originate in the fact, that the former species of charity will be sure to pay in the long run, in some way or another, while the latter could

have no possible reward, except in the approbation of the conscience. Far be it from me to suppose that this backwardness could have its origin in that jostling rivalry of an overstocked profession, in which each one becomes jealous of his neighbour getting a slice from his own loaf, and, therefore, does not cultivate the finer feelings of friendship and kindly feeling towards others in the same pursuit. I can scarcely think that such motives can operate extensively; and I would really believe, that ignorance of the extent of the evil, and forgetfulness of the time for applying the remedy, are the great efficient causes of the neglect, which in itself is undeniable.

Be it ever recollected, however, that these are *criminal* causes,—that their influence is deeply culpable,—and that he who neglects to relieve distress, is but a shade less guilty than he who occasions it.

I propose to pass in review in this paper the several methods which have been devised for the relief of professional distress. These all may be referred to a two-fold principle,—prudence on the one hand, pure benevolence on the other. I would by no means assert, that the plans which have been grafted upon the *former principle*, have not derived their source from the benevolence of their originators, or that there is not a large amount of charity in the hearts of their supporters. But the principle is a different one, and is most obvious: the one being to *provide* for one's own necessities as well as those of others, upon the mutual principle of all provident institutions, that those who do not require assistance will contribute towards those who do; while the second or purely benevolent principle, is one which associates around it those who have no selfish or mutual interest in the institution, but who combine to relieve the necessities of those who are *unprovided for*.

It may indeed be said, that there should be no one unprovided for,—that every one should have made a store during the summer of his days, against the contingencies of his age, and the winter of sickness,—a species of argumentation very common with Poor-Law Guardians, since poverty has been treated as a crime. We are quite disposed to admit that there is a general and prevailing improvidence amongst us as a body; and that by early marriage,—by a very pardonable desire to keep up appearances of respectability,—by a certain degree of hospitality which can be ill afforded,—by the effort to give one's children education suited to the advanced and still progressive state of knowledge around us,—by the wish that our children should advance rather than retrograde from their social position,—and by little personal indulgences which are not strictly consonant with that rigid and parsimonious economy, which alone can make our ill-requited services adequate to the yearly expenditure, we may really dissipate that which might have been laid up for a rainy day. But, after all, this is parallel with the poor man, who during the winter's want of work, gets into debt for the necessities of life, hoping during the summer, by longer days and increased exertion, to clear off his debts, and to obtain clothing for his children. And perchance he may do so; but if illness,

or misfortune, or the want of work befall him, he is pauperised, and requires relief. And so, if illness in his family, or infirmities, or losses, or changes in the neighbourhood, or a thousand other fluctuations, interfere with the due supply of income, then does the medical man become incapable of *providing* for himself,—then does he become dependent upon the aid of others.

There must always be two classes of misery,—the one, which may relieve itself by mutual combination; the other, which can only be relieved by the gratuities of those who can spare something from their riches, or out of their deep poverty, for the relief of others still poorer than themselves. We shall consider first the several ways in which persons may provide against their own necessities.

I. By life insurance. No prudent and unselfish person should neglect this method of providing for his family, in the event of their being deprived of his support, and of the income arising from the continuance of his exertions. It is, however, obvious that this is a purely unselfish proceeding, and that the insurer himself can derive no return for the privations to which he may be subjected in order to furnish the annual premium; his compensation consists in the most agreeable thought of taking every possible care of his family, and saving them from dependence upon a selfish world. It is also obvious that they only are benefitted by life insurance who die early, and that they who live to advanced age would have done better by having been their own insurers, and by having accumulated their own premiums, and improved them at compound interest by a yearly re-investment. It may indeed be true, that if the removal of the premium at a given period were not a matter of *necessity*, the money would in all probability be spent, instead of being invested. Considering this, therefore, and also the uncertainty of the continuance of life, so that no person can presume upon himself as long-lived, it may be fairly said that every professional man should insure his own life, according to his ability, not, however, too largely, since the event of his living incapacitated by illness, the continuance of his premium may become a very heavy difficulty to himself or his friends. An instance of this kind occurred to a very eminent physician of his day, who, in the hour of his greatest prosperity, had insured his life for £20,000. He was attacked by paralysis; never earned another guinea; and it was only by the very great exertions of his family (those most interested it is true) that the life policies were kept afloat for the seven yet remaining years of his life.

Admitting, then, the principle, that every medical man should insure his own life for the benefit of his family, the kind of office he should select is not a matter of *indifference*, because his object should be the most ample security, at the least possible rate of premium. An Insurance Office upon the *strictly mutual principle*, giving *no commission* to agents—spending very little upon advertisements—depending for extension upon the influence of mutual good feeling,—with a board of directors of known probity and worth, and responsibility,—and *diminishing* its premiums after the

first five years, should be the office to be chosen. The only office *approaching* this description among ourselves is the Medical, Legal, and General; and, with some little modifications, this has an especial claim upon our patronage, and then it would soon be placed in a very elevated position. Still, in order to realise my *beau idéal* for a good Insurance Office, it must *allow no per centage to agents, and it must diminish its rates of premium after five payments*. It should ever be remembered, that all the expenses of agency (at least five per cent.) are so much over and above what is necessary to represent the actual risk to the Society, and is, therefore, over and above what is necessary to *security*. And to make these plans quite safe to the office, there is only wanting an *esprit de corps*, a spirit of mutual interest, and a desire to promote mutual-kind offices,—a spirit which we may rather hope for in future than proclaim its present existence.

II. Some provision may be made for his own declining years by purchasing a deferred annuity, to commence at 60 or 65, so as to furnish him with some extraneous income, when his own professional energies begin to fail, or to be trenched upon by the younger and more active competitors.

III. Another form of providing for the future, is the purchase of an annuity for a widow when she becomes such; or of a joint annuity, to commence at the failure of the first life, whichever it might happen to be,—the latter plan realising the double object of providing for one's own feebleness, should it occur, and for a widow should our own life fail.

But these intentions cannot be fulfilled without a very considerable outlay: they can only be fulfilled by an accurate appreciation of the value of life—and where a sufficient amount of premium is given to cover the risk of professional existence. If this be not carefully attended to at the outset, disappointment must inevitably occur. Money cannot be made to multiply itself by any species of spontaneous generation, or by any other than ordinary means; it is at all times a sufficient risk to run, that the annuity, so purchased, may never be available to either of the parties, and therefore, that the money so advanced would be entirely lost; but this risk is not equal to the disappointment, that although the circumstances have occurred, the consequences have not followed. This is the great evil attaching to an annuity fund propounded by a most benevolent individual, whose sanguine calculations have led him to the belief, that a yearly guinea will secure annuities of £20 or £25 a year to as many claimants as may happen. Here everything will seem smooth for a few years, till the laws which regulate mortality, bear upon results, and then it will be found to fail from the want of a due appreciation of the risk incurred in a society where, ultimately, the great mass of mutual annuitants will consist of those who expect to derive a probable benefit from its agency,—where no difference of payment is made according to the age of the individual,—where no accurate calculation has been established for the difference of risk in the single and married,—nor of the age of the wife; and where, on the first occasion

that there are four annuitants to be chosen, and there are five candidates, all these candidates must be submitted to the humiliating necessity of canvassing every one of the subscribers in order to secure a preponderance of votes; and after all, one of the five must inevitably be disappointed.

IV. Another method of providing for futurity, is, by the endowment of children, so as to receive a certain sum at a certain age, in the event of each child reaching that age, the term being fixed for the most expensive period of education,—or for the first outfit in life,—or for an apprentice premium,—or marriage fortune,—or any other similar contingency. All these, however, involve a considerable outlay, and it is doubtful whether any ordinary professional income can afford such an outlay. Probably *one only* of these several methods of provision must be selected; and if so, undoubtedly life insurance should be that one, except in extreme cases, where the widow and children have been ultimately provided for by marriage settlement, or some such arrangement, but where cash is wanted from the present annual income, to provide for the education of the children who shall be at college, or requiring an expensive outfit, during the lifetime of the father.

V. It is very much to be regretted, that no institution yet exists among ourselves, whereby sickness of more than a temporary character could be provided for, and the expense of an assistant could be met, or the wants and the comforts of declining health could be provided for. Several instances of this kind have occurred to me within the last year, where the health has been irretrievably broken,—where, for three, four, five, or even more years, the last days of the husband have been watched over most affectionately by a wife, who, at his death, and on her first entry on the rugged path of widowhood, would have spent the last shilling, and be found pauperized—actually dependent for bread, upon the tender mercies of a Board of Guardians. This extreme state of destitution could have been provided against by an insurance for sickness, after the manner of benefit societies, only upon juster calculations, and more in accordance with the principles of the Clerical Institution. The last few years of my life, have been partly given towards effecting an institution of this kind, ever since my letter to the Journal, written from Bedgellert, in August, 1843. Hitherto no successful result has issued, but with my firm character, “Hope on, Hope ever,” is my motto, and “*nil desperandum*” is my badge.

VI. Another method of providing for the future, is by belonging to one of those excellent institutions, which offer certain advantages to their members, arising from a certain number of their own subscriptions, and from the additions made to such subscriptions by members who have no prospect of participation, and whose only object is to do good to their less fortunate brethren. These institutions partake, therefore, of a mixed character; they are *provident* in so far as regards their members who may become claimants by themselves or their families; they are *benevolent* in so far as regards those members who are subscribers purely for

the good of others; and their design is excellent, though limited.

There are before me ten laws and reports of eight institutions of this kind in the metropolis and different sections of the provinces. It had been my design to have given an enlarged statistical view of the operations of these societies in their several localities, and to have gone fully into their respective merits and agencies, but I have not been able to obtain such precise information as to their *boundaries*, their management, and the relative proportion of subscribers to the mass of practitioners within the district embraced, or of those who might probably become claimants upon the fund, to enable me to do so with precision, and I must, therefore, content myself with some general observations.

It may be remarked of all these, and affiliated societies, that their *permanent efficiency* must depend upon the maintenance of a due proportion between the available income and the claims made upon the funds; and it would appear that these institutions had been managed with such an amount of prudence, and such an apportionment of the annuities granted, that up to this time their resources have been found ample, and their capital has accumulated.

And since it is not often that we find institutions of this nature becoming rich, where the chances have not been nicely calculated, it becomes us to inquire into the causes of this wealth, and especially to ascertain if the reference be legitimate, that it is because they are not *actually and practically required*. For a reply to this question, I would refer to the published opinions of the secretary of the largest of them, for London and its vicinity, who feelingly laments the frequency with which he is assailed by claimants, to whom he is obliged to reply that they cannot be relieved, because they are not *members*, or the representatives of such. The reason, therefore, of the accumulation of capital, is, not that there is not widowhood and orphanhood in abundance to be relieved, but that the widows and orphans have no title to relief under the present constitution of these societies, *except by membership*; indeed, on looking over the list of contributors there are certain things which cannot fail to strike the observant eye; as, first, the *immense preponderance* among the members, of those who cannot, by any positive calculation, be supposed to have subscribed for themselves, but only as an act of charity towards others, who, less fortunate than themselves, may become claimants.

Secondly, separating those who cannot, by any ordinary contingency, become claimants upon the fund, we are next surprised at the *small number remaining*, of whom it may be supposed that *their* widows and orphans may become dependent for aid, and who may be said to have become members with the provident intention, of laying up in store for those who may be left behind, in the event of their early death; and when it is recollected that *comparatively few* of these will die before their wives, or leaving children unprovided for under *fourteen* years of age, or not leaving behind them an income of £50 a-year, we cannot be astonished that the income of these societies should exceed their expenditure.

Thirdly, we are surprised, by the very small number of subscribers of both classes, as compared with the number of medical men living in their respective localities. Here the disproportion is so enormous, as to lead to the conclusions that the proportion of medical men with superabundant incomes is very small; that the number of those who will save from scanty incomes for charitable purposes, by acts of self-denial, is still smaller; that the number of those who avail themselves of these institutions as a provident resource is very limited; that amongst the mass of medical men, there are some *who could, but who will not*, provide for their families, because they prefer the enjoyment of their own little luxuries, (*Curpe diem—minime credula postero*;) but there is also a very considerable number who cannot, by the most rigid economy, carry this self-denial privations further; and who cannot, let the consequences be what they may, spare the cost of membership to any of these valuable institutions.*

There is then a class of sufferers who have no refuge in these amicable societies, and there is a class of distress to which they are utterly inapplicable; and for these sufferers, and for their families, and for their distress, so shut out from all other aid, THE BENEVOLENT FUND is provided.

(To be continued.)

NOTES ON AMERICA: ITS MEDICAL SCHOOLS AND ESTABLISHMENTS.†

By EDWARD HUMPAGE, Esq., M.R.C.S., Bristol.

The other Medical School to which I referred is connected with the College of Physicians and Surgeons, although not so large as the University Medical School. It is well conducted, and numbers among its professors some very able men. The lectures commence in November, and continue four months. The Museum of Anatomical Preparations and Morbid Specimens is well arranged and extensive; it contains also some fine models of skin diseases, executed by the late Doctor Thenard, of Paris. I was particularly struck with those representing that horrid disease—glanders, in the human subject.

The number of students this session was above 200: they appeared very well conducted persons, differing in no essential particulars from our own medical classes but in that most disgusting and filthy practice of chewing tobacco, the effects of which were everywhere apparent, and brought to my mind the philippic of James I., in which the royal author, speaking of tobacco, says—"It is loathsome to the eye, as well as harmful to the brain." I must not, however, be understood as stating, that all the medical students I saw in the schools practised this abomination; there were, happily, many gentlemanly exceptions, but, alas!

* On the subject of provision for families, see a valuable paper by Dr. Holbrook, of Cheltenham, which will be inserted in a subsequent number of this Journal.

† Continued from page 136.

the floors, the staircases, the lobbies of lecture rooms, told a tale of tobacco, and spoke of *salivary stimulation*, too plainly to be misunderstood.

But I turn from this digression, to speak with pleasure of the politeness with which the lecturers in this school received me. The chemical professor, Doctor Torrey, the professor of anatomy, Doctor Watts, and the professor of surgery, Dr. W. Parker, were exceedingly kind; and I had much satisfaction in attending the last gentleman's surgical clinique, delivered to the class every Monday, from eleven o'clock until one, p.m.

Dr. Parker has been in Europe, is an accomplished surgeon, in middle life, and enjoys a deservedly high reputation among his medical brethren and the citizens of New York. He is a good medical surgeon, if I may so speak, and prefers ankylosis, with all the trouble of obtaining it, to the more brilliant and *far easier* plan of getting rid of the disease by amputation. I attended this gentleman's clinique on two or three occasions, and some of the cases I will now relate.

The first person who presented himself was a man aged 35, suffering from diabetes; this patient passed more than two gallons of saccharine urine daily; he was very thin, of a cadaverous aspect, had lost his virility, and suffered from great thirst. The supposed cause of his disease was indigestion, from drinking bad water at New Orleans, from which city he had recently come. Dr. Parker gave the class a very concise history of the various theories and plans of treatment which medical men had proposed, but he still regarded its pathology as *sub judice*, and its treatment as empirical. In this case he recommended animal food, and simple drinks,—as cocoa, milk-and-water, and occasionally small doses of potash, tincture of iodine, warm baths, and Emplastrum Belladonnæ constantly over the loins.

Hemiplegia Dr. Parker treats with considerable success by strychnine.

Dr. Parker's comments on a case of phthisis were highly practical. The patient was subjected to a good examination, both as to the physical signs and also the constitutional; much stress was laid on a due observation of each class. Among the former symptoms he appeared to attach much importance to the effect of tubercle, producing *increased resonance* from the superior conducting medium through which the sound passes. He places much reliance on the use of the spirometer, and stated his experience as to the curability of the disease to be, that out of seventy-three cases twenty recovered, the patients getting well being for the most part thirty years of age.

"I know," said the Professor, "it is a *squally* position to be placed in, to have tubercle in the lungs, but it is curable by good food, fresh air, and an *equable* temperature, not hot, but even as low as 40° Fahrenheit if you please. Hence the climate of Canada is far better than that of New Orleans. I go for out-doors in these cases, rather than apartments regulated at an artificial temperature. Make your patients take much passive exercise, as on horseback, or at sea. This was old Sydenham's plan."

A case of tumour of the lower lip presented itself in a great smoker. Dr. Parker remarked that it was

encephaloid, and not *scirrhus*. "We must fix it,"* said he, and forthwith the operation was very neatly performed.

The other cases on that occasion were ovarian dropsy, ascites, and diabetes, concerning all of which Dr. Parker spoke in a manner well calculated to impress his auditory with the soundness of his judgment, and the practical quality of his observations.

In a case of paralysis (from lead,) of the extensors of the wrist and fingers, he directed the attention of the class to the characteristic *blue line* round the gums, and suggested, as the best treatment, good diet, constant support, with an India-rubber splint, and the occasional application of electricity.

(To be continued.)

General Retrospect.

PHYSIOLOGY.

EXHALATION OF CARBONIC ACID IN HEALTH AND DISEASE.

The following conclusions are arrived at by M. Hervier. :—

In a Healthy state of System.—1. The exhalation of carbonic acid varies from hour to hour, with the variations of the barometer, the maximum being at nine in the morning and eleven at night; the minimum, at three in the afternoon and five in the morning.

2. The variations in temperature and barometric pressure are in inverse ratio as regards the exhalation of carbonic acid.

3. During digestion the oxygenation of carbon is diminished. The ingestion of animal food diminishes the quantity of expired carbonic acid; the reverse is the case with vegetable food.

4. In running the expired air does not contain carbonic acid.

5. It is the same after the inhalation of æther and chloroform, and after the use of alcoholic beverages.

6. During sleep less carbonic acid is expired than in the waking state.

7. The air expired by infants contains a larger proportion of carbonic acid than that breathed by adults.

In a Pathological state.—1. In meningitis and other well-defined inflammations, the quantity of expired carbonic acid is increased.

2. Pneumonia, pleurisy, pericarditis, &c., are an exception to the rule.

3. Persons labouring under rheumatism expire an increased quantity of carbonic acid.

4. More is evolved also in intermittent fever, and especially in the hot stage.

5. Less carbon is consumed in the eruptive fevers, in scorbutus during suppuration, and in the syphilitic cachexiæ.—*Gazette Méd.*, Feb. 24th.

* A curious Americanism, meaning, in plain English, we must remove it.

PATHOLOGY.

ANEURISM OF THE CORONARY ARTERY.

Dr. Bevill Peacock reports a case of this rare lesion, premising it with the account of the only two cases he is able to find; one published in the *Bibliothèque Méd.*, 1812; the other in the *Archiv. Gén. de Méd.*, 1843.

A man, aged 51, a butcher, admitted into the Royal Free Hospital, in December, 1847, labouring under influenza, formerly of irregular habits. When examined, he was much collapsed, with severe cough; pulse 144, feeble; tongue furred. Auscultation revealed the crepitation of the prevailing epidemic. He was cupped between the shoulders, and took ipecacuanha, with compound spirit of ammonia and paregoric. On December 4th, he was slightly better, and for three days continued to improve, but he then became more torpid and feeble. A more stimulating treatment was substituted, together with a blister to the chest. On the 12th he complained of pain in the left side of the chest, pulse 120, intermittent. There were loud sonorous rhonchi; and in the region of the heart a peculiar sound like that of beating egg with a spoon. This disappeared next day, when he died.

Post-mortem examination. In addition to emphysema of the lungs, the pericardium was found to be distended with sero-purulent fluid, with lymph of soft consistence. At the upper and outer part of the left ventricle, there was a protuberance the size of half a walnut, which was found to be an aneurism of the coronary artery. The cavity of the aneurism was filled with coagulum; the other artery was ossified.—*Edinburgh Monthly Journal*, March, 1849.

PATHOLOGICAL APPEARANCES IN CHOLERA.

The alterations observed by M. Virchow, in the intestinal canal consist in an uniform invasion of the entire mucous membrane, without any special affection of the glandular apparatus. It is true that the solitary glands are sometimes diseased as well as those of Peyer, but these lesions are far from constant. The changes in the mucous membrane itself are very like those of diphtheritis, commencing in intense hyperæmia, with extravasation of blood, and the exudation of a whitish membrane. At this period the microscope exhibits an amorphous granular matter, interposed between the fibres of the mucous membrane, which becomes partially sphacelated. These changes are mostly seen at the lower end of the small intestine. It should be remarked that these diphtheritic appearances were not constant.

The intestinal secretions sometimes contained albumen, at others only saline ingredients. The mesenteries were almost constantly infiltrated with a peculiar whitish granular matter.

The author also frequently met with engorgement of the spleen, but this was chiefly among boatmen, many of whom had been the subjects of intermittents.

The stomach was not remarkable for any constant morbid appearance, it was generally distended and intensely injected. An epithelial exfoliation was

always seen in the duodenum, and its villi were often infiltrated with fatty matter. The gall-bladder always contained an abundance of bile. The liver was pale and exsanguine. The calices of the kidney exhibited capillary injections, with increased epithelial secretions. The bladder was always empty, and closely contracted. The lungs collapsed on opening the thorax; their inferior lobe was often engorged. In several cases the author found interlobular emphysema. The pleura was sometimes covered by patches of false membrane. The heart was pale, and rigidly contracted on the left side, but the right cavities were always gorged with dark coagulated blood, mixed with fibrinous concretions, in which were globules resembling pus. The veins were generally gorged with black blood, while the arterial system was empty. The heart was always healthy.

Such were the appearances in the algide period of cholera. In cases which died during the typhoid period, signs of inflammation with exudation were observed in various organs. It was at the commencement of this stage that the diphtheritic patches were commonly noticed, both in the intestines and in the vagina, especially when the patient had been seized during menstruation. The lungs sometimes exhibited apoplectic extravasations. In the kidney there were often seen the appearances indicative of acute albuminous nephritis.—*Gazette Méd.*, Jan. 20th.

PRACTICAL MEDICINE.

ON INUNCTION WITH LARD IN SCARLATINA.

The following plan of treatment in scarlatina is advised by Manthner, an undeniable authority in diseases of children. He observes :—"I owe to M. Schneeman an excellent method of treating scarlatina, and one from which I have derived the best results; this is, the inunction of the entire surface with lard. These inunctions never do harm; they are cheap, and may be employed by all classes. I am confident that they cause desquamation to take place more readily, and that dropsical sequelæ are less likely to occur. Moreover, if used as a prophylactic, the disease is less likely to spread in a family. I would, without hesitation, treat my own children in this manner, where they attacked by a disease which I so much dread, but I should fear to employ cold affusions.—*Rev. Méd. Chir.*, Jan., 1849.

EXPRESSED JUICE OF THE COTYLEDON UMBILICUS IN EPILEPSY.

Mr. Salter, of Poole, narrates an instructive case of severe epilepsy which, after resisting orthodox treatment, yielded to the above remedy, prescribed by an extra-professional adviser. The plant, which belongs to the order Crassulacæ, is allied to the genera *Sedum* and *Sempervivum*, and is found generally growing on shady damp rocks. It figures in a Herbal, published by Elizabeth Bakearch in 1737, as being beneficial in liver and kidney diseases, in piles, &c.

The extract of the plant is stated to have been used successfully by Dr. Bullar, of Southampton, who will

one day publish his experience of its action.—*Medical Gazette*, March 2nd.

TREATMENT OF NEURALGIÆ ACCORDING TO THEIR SEAT.

[The author, M. Sandras, passes successively in review neuralgia of the fifth pair of the cervical plexus, ilio-sciatal neuralgia, crural and sciatic neuralgia. His treatment is expressed in the following *resumé* :—]

Neuralgia of the fifth pair yields more readily than any other to the internal administration of belladonna. He has also derived benefit from a plaster of the black cyanide of potassium. The pomade of strychnine has only appeared useful when, after the attack has subsided, the skin has retained an exaggerated sensibility.

In temporal neuralgia, with the employment of belladonna internally, he conjoins compression of the temporal artery.

In suborbital neuralgia, the endermic use of morphine, and the cyanide of potassium, succeed better than in temporal or cervical neuralgia.

In submaxillary neuralgia, belladonna is the most useful remedy; compression of the carotid likewise affords relief.

The same treatment is beneficial in cervical and occipital neuralgia, but in this form compression of the artery is of little or no use.

The treatment is likewise the same in intercostal crural, and sciatic neuralgia, but the author observes that these forms are often accompanied or produced by neuritis, and that it is therefore advisable to premise the treatment by topical abstraction of blood.—*Gazette Médicale*, December 30.

SURGERY.

ANEURISMAL TUMOUR OF A BRANCH OF THE EPIGASTRIC BURSTING INTO THE SCROTAL SAC.

The following case is narrated by Dr. Kreider, of Lancaster, Ohio, U.S. :—

George Hanstein, aged 48 years, stone-cutter, presented himself for relief, June 27th, 1841. About twelve years ago, while engaged in turning a large granite block, one corner of the stone came in violent contact with the os pubis, on the left side of the root of the penis. A stinging pain was felt for some time after the accident. A few days afterwards, a small pulsating tumour (about the size of a hazelnut,) was found to occupy the seat of the injury. This tumour very slowly enlarged ever since that time, until it attained the size of a large hen's egg. It has at no time been a source of much inconvenience. A week since the man went to bed as usual. About midnight he awakened suddenly, feeling a stinging pain about the place of the tumour, and putting down his hand to the part, was surprised to find that the tumour had disappeared. He soon, however, discovered that the scrotum was much enlarged, and that this enlargement was rapidly augmenting. The following are the dimensions of the scrotum at this time :—Length, two feet; circumference near the apex, seventeen inches; at the middle, twenty-two inches. Upon making an incision into the scrotum upon the left side, a large quantity

of partially coagulated arterial blood escaped. Finding that hæmorrhage still continued, I dilated the wound upwards, and found the bleeding vessel to be a branch of the epigastric, the vessel which had been originally injured, forming an aneurism, whose walls giving way, had suffered blood to escape and find its way into the scrotal sac. The vessel was secured by ligature; the coagula entirely removed from the scrotum, and the wound closed by interrupted sutures and adhesive strips. Some slight suppuration followed, but in a few days the parts healed, and the man speedily and perfectly recovered.—*Ohio Med. and Surg. Journ.*, Nov., 1848.

CASE OF VOLVULUS CURED BY GASTROTOMY.

The subjoined case is interesting as an illustration of the value of surgical aid in a class of internal diseases, which if left to themselves almost invariably terminate fatally :—

L. S., a man of strong condition, aged 30, the subject of right inguinal hernia, exerted himself in lifting a heavy burden after having eaten a large quantity of cherries without rejecting the stones. While thus employed he felt a pain in the lower part of the body, which soon extended over the whole abdomen. On being removed to hospital it was discovered, not as was expected, that his hernia had become strangulated, but that a tumour the size of the fist was found in the right iliac fossa. Although there was neither vomiting nor absolute constipation, the surgeon suspected a volvulus. The presence of some obstruction was soon after rendered certain by the occurrence of all the symptoms of strangulated hernia, and after the ejected matter had become stercoraceous, an operation was decided upon.

The patient accordingly being authorized, an incision was made of four inches in length; the peritoneum being carefully opened the intestines were found to be extremely distended; the tumour was formed of the ileum near the caput cæci, one loop of which had completely encircled another, which contained several cherry stones, and was so firmly constricted that its liberation was impossible. This being the case, the operator divided the constricting loop, and the strictured part being set free the wounded intestine was united by suture and the parts replaced.

The after-treatment consisted in the local application of ice, and its use internally. After a few days a dose of castor oil was given, which brought away a large quantity of cherry stones *per vias naturales*. Subsequently, however, sloughing took place, and fæces escaped through the abdominal incision, but in spite of this untoward event the man recovered.—*Il Raccoglitore Medico*, Sept. 1848.

IMPROVED OPERATION FOR CONGENITAL PHYMOSIS.

The operations proposed for the above defect are—1, circumcision; 2, simple incision of the prepuce over the surface of the glans.

The objections adduced by Mr. Colles to circumcision are, that from the greater retraction of the outer fold of the prepuce, a second proceeding is necessary to free

the more adherent inner fold; and that from the contraction after cicatrization, great pain arises during erection. As an improvement on the ordinary method, Mr. Colles advises the following:—

He seizes the edge of the prepuce in the left hand, and holding the scalpel in the right, and at right angles, he removes a circular portion of skin, about a quarter of an inch wide; the outer fold of skin is then drawn back, leaving the glans still covered by the inner fold. He divides this layer about half way back, directly up the centre. He then turns the two angular flaps thus made, outwards, and unites each angle to the outer skin, about a quarter of its circumference from the frenum. A slight suture at the frænum completes the operation. The part is then drawn forward, so as to cover the glans. In two or three days union takes place, and so little deformity results, that in some cases it would not be known that any operation has been performed.—*Dublin Quarterly Journal*, Febr., 1849.

CALOMEL AS A LOCAL APPLICATION TO CHANCRE.

Dr. Hartshorne dresses obstinate chancres and ulcerated buboes in this manner. After sprinkling calomel freely upon them he covers them with lint dipped in a solution of chloride of soda.—*American Journal of Medical Science*, Jan. 1849.

OBSTETRIC MEDICINE.

UTERINE INJECTING APPARATUS.

Dr. Jones has devised an apparatus for injecting the vagina and other canals, which deserves to be extensively known, from its simplicity and cheapness. It consists of a vagina or other pipe, connected with gutta-percha tubing, divided into two lengths, one of seven feet and a quarter, the other of one foot and three quarters. To one extremity of the longer portion a lead weight is attached, and to the other end the male portions of an union joint, made of box. To the corresponding end of the shorter portion is affixed the female portion of the joint, and the other end is adapted to the vagina or other pipe. The mode of using it is, first, to introduce the pipe into the vagina, with the shorter portion attached, the patient sitting over a bidet, or other convenience. The larger portion is inserted by its weighted end into a tub or vehicle containing the injection, and placed at a corresponding height above the patient. The tube is then exhausted by an inspiration, and rapidly inserted into the other. The fluid immediately flows in a continuous stream to any quantity that may be required. The apparatus is improved by the use of a speculum, with a lid pierced with two holes, one for the insertion of the vaginal pipe, the other for a tube to act as a waste pipe. By this means a douche can be thrown directly on the os uteri. A modification of the pipe adapts the apparatus for injecting the rectum, external ear, &c.—*Lancet*, Febr. 17.

MEDICAL LEGISLATION.

MEMORIAL TO THE RIGHT HONOURABLE SIR GEORGE GREY, BART., M.P.

The undersigned Members of the Medical Profession, practising in Manchester and its immediate neighbourhood, beg to express the gratification which they feel at the interest you have evinced in the subject of Medical Legislation, and to offer you, at the same time, their best thanks for the efforts you are making to bring about a satisfactory settlement of the question.

They feel bound, however, to offer you the very serious objections which they entertain to a scheme proposed for the purpose, embodied in certain "Outlines of a Bill for regulating the Profession of Physic and Surgery," which is contained in a "Report on the present state of the Medical Reform Question, published by the Council of the National Institute of Medicine, Surgery, and Midwifery," which Outlines, it is stated, have been submitted to you by a conference of delegates from the principal Medical Corporations in London, as likely to be acceptable to the profession at large.

The undersigned Memorialists would observe, in the first place, that no satisfactory reasons exist for the establishment of a College of General Practitioners in England, when no corresponding institution is proposed for Scotland and Ireland; and they see, moreover, no good reason why any such incorporation should be proposed at all. It has been urged that the Royal College of Surgeons of England, unlike that of Scotland or of Ireland, has always been an institution for the promotion of Surgery merely, on which account the Council have constantly repudiated any arrangement whereby future members of the College should undergo some comprehensive examination in all the sciences, an acquaintance with which is more or less required in the several exigencies of medical and surgical practice. The undersigned, however, would submit that the voice of the great majority of the profession, and the all but unanimous disposition of members of the College, should be paramount to the antiquated conceptions of certain members of the Council; and they would urge that the English College, either by legislation, or by royal charter, should be so far assimilated in its constitution to those of Scotland and Ireland, that one scheme of medical polity should uniformly apply in every part of the United Kingdom.

The undersigned would urge upon you, that any alteration in the constitution of the English College of Surgeons, at the instance of its virtually irresponsible Council, is deemed by them to be quite out of the question, and yet without an alteration in its present constitution, harmony between the College and the great body of the profession cannot be re-established. They would recal your attention to the circumstance, that legislative enactments, some years ago, harmonised municipal institutions with the spirit of the age, irrespective of the feelings of irresponsible councils; and they would submit, that no grounds exist for the application of a different principle in the treatment of Medical Corporations. But even if it were conceded that the establishment of the College of General

Practitioners in England were a necessary or a good thing, the undersigned maintain that the kind of institution proposed would fulfil none of the ends for which such a College has been stated by the conference to be required; for, by the draft of the charter which is solicited, it is proposed to admit doctors and bachelors of medicine to the membership, without any further examination, in this way leaving the public, to whom they thus become certificated as general practitioners, without any guarantee for their practical efficiency in midwifery or pharmacy, and giving them, moreover, equal advantages with those who have been examined in every department of the profession. The Memorialists would observe, that attendance upon lectures, without the expectation of examination on the subject of the same, is notoriously a mere formality. A still greater anomaly exists in the proposal to enrol, in the College of General Practitioners, persons holding the diploma of the English College of Surgeons, seeing that it is merely a testimonial of anatomical and surgical proficiency; but if this circumstance were passed over as a mere temporary evil, necessary for the adjustment of certain existing anomalies, the proposed scheme of the conference would permanently establish the practical absurdity of authorising the Fellow of the College, without any medical examination whatever, not only to practise every department, but further to do so with the prestige of superior rank. If then the Council of the College of Surgeons be sincere in its declarations, that its purpose is merely to educate anatomists and practitioners in what is called pure surgery, it is a flagrant injustice to the community at large that they should thus confer privileges to practise the profession generally.

The Memorialists hold, that if a College of General Practitioners is to exist at all, it should be for the three kingdoms, and as a common portal to all who enter the profession with the intention of practising the same in all its departments; and they would remind you that, except in the metropolitan and some other of our leading cities, almost all members of the profession are general practitioners, whatever be their academic or collegiate distinction.

The Memorialists would further observe, that no legislation can be acceptable to the great body of practitioners in England, that may in any way ratify the arrangements introduced into the College of Surgeons by the charter of 1843. In remedying the retrospective injustice perpetrated by that enactment, they would urge you (in any Bill that may be introduced), to abolish the distinction in the register to be made between Fellows and those who were members prior to the grant of the charter in question. They would more especially urge upon you, that the distinctive classification of a register should have regard not only to collegiate rank, but to the actual circumstances of practice; for example, that to be registered as physician, the doctor or bachelor of medicine should practice in that capacity,—that to be registered as surgeon, the fellow or member should at least cease to dispense his own medicines,—and that all, whether doctors of medicine, fellows or members of colleges, should be required to register as general practitioners, if such be their actual position.

The Memorialist, however, would again submit, that for all purposes benefitting science or the community, there is no requirement for any additional college, and that no practical advantage can result from any such three-fold classification in the proposed register as that just referred to; because, out of London, the actual condition of the profession would be found to have no reasonable correspondence with the same.

They would, in conclusion, earnestly entreat you to decline becoming a party to any legislation in the spirit set forth in the "Outlines of a Bill" published by the Conference of Delegates. They have to state, moreover, that if, unfortunately, from the extraordinary activity and perseverance of a very small minority of the profession, any such Bill should pass into a law, members of the English College of Surgeons will, in many cases, feel bound to decline being placed on the register altogether, rather than to occupy therein an unjustly subordinate position. The Memorialists sincerely hope that the members of the College will not be driven to so extreme a proceeding; but they are convinced, at the same time, that if the course of events should call upon them to take such a step, they will not hesitate to do so.

Signed by 142 leading members of all classes of the profession, residing in Manchester and its immediate neighbourhood, including—Edmund Lyon, M.D., J. L. Bardsley, M.D., Consulting Physicians to the Manchester Royal Infirmary; W. J. Wilson, F.R.C.S., Senior Surgeon to the Manchester Royal Infirmary; Thomas Radford, M.D.; John Windsor, F.R.C.S.; John Robertson; W. W. Bevan; Daniel Noble; R. H. McKeand; George Southam; Thomas Dorrington; J. B. Harrison; F. Renaud, M.D.; J. Black, M.D.: A. M. Heath; Jos. Denham; John Rayner, F.R.C.S.; Thomas Fawsitt; J. Yorke Wood, &c. &c.

LOCAL APPLICATION OF CHLOROFORM IN OTALGIA AND ODONTALGIA.

"A Correspondent" recommends the use of chloroform in "otalgia and odontalgia," in both of which he has never yet known it fail in giving instant and permanent relief. In "otitis," and in the painful rising of the teeth in children, before they are sufficiently near the surface to obtain any relief from lancing the gums, he has found the most pleasing effect, producing, in most cases, that quiet and refreshing sleep showing the freedom from pain. Its application is simple. He says,—“In the former simply scrape a little lint, drop a drop or two of the liquid on it, and apply to the ear or tooth; in the latter I rub the gums with the finger moistened with the liquid, and the effect is immediately manifest. I have used it in the form of gargle, in cyanche, when it has been accompanied with severe pain, with such good result, that I feel convinced if once or twice tried, its use will soon be general. One drachm, to one ounce of distilled or rain water, is the proportion for the gargle. If you have not used it in neuralgia, more particularly of the face and eyebrow, I think you will find it worth the trouble to saturate a piece of lint with it, and apply it to the painful part.”

COD-LIVER OIL IN PHTHISIS.

Dr. Ranking, of Norwich, is collecting evidence respecting the value of cod-liver oil in phthisis, and would feel particularly obliged to any members of the Association who will favor him with the results of their experience. The names of such contributors will be scrupulously given on publication, in connection with their contributions. The points to which he would respectfully direct attention are—

Number of cases, successful and unsuccessful.

Stage of the disease in different cases in which it was exhibited, as marked by the physical signs.

Degree of amendment produced, and its duration.

Quality, dose, &c., of the oil.

General effects as regards diminution of night-sweats, expectoration, and increase of weight, &c. &c.

Any other information deemed valuable.

Medical Intelligence.

TESTIMONIAL TO MR. THOMAS HUNT,

OF BEDFORD SQUARE, LONDON, (LATE OF HERNE BAY.)

An elegant silver salver has been presented, by the inhabitants and visitors of Herne Bay, to Thomas Hunt, Esq., surgeon, on his removal from that place to London, "as a memorial of his professional ability, and personal kindness and attention, during a period of twenty years."

AMERICAN ESTIMATE OF NATIVE MEDICAL LITERATURE.

It cannot be denied that the great *forte* of American medical scholarship has hitherto consisted in "editing" the works of British authors. The Committee are not disposed to deny the fact that this business has been carried on in every shape and labour-saving fashion. A tacit alliance between writers and publishers has infused the spirit of trade into the very heart of our native literature. The gilt letters of the book-binder play no inconsiderable part in the creation of our literary celebrities. Sometimes the additions by the "American Editor" have been real and important; oftener nominal and insignificant. The following calculations of the proportion added to different recently-published works taken at random, will show the average amount of material so contributed. The editor's proportion was, in two instances, one-fourth; in two more one-eighth; in one, one-ninth; in another, one-tenth; in others, one-fifteenth, one-seventeenth, one-nineteenth, one-twentieth, one-twenty-eighth, one-fifty-ninth, one-sixty-fifth, one-ninetieth, one-hundred and seventh, and in one instance, such a sprinkling as a single penful of ink might furnish, and leave enough to spare for a flourishing autograph. The fairest fruits of British genius and research are shaken into the lap of the American student, and the great danger seems to be, that in place of the genuine culture of our own

fields, the creative energy of the country shall manifest itself in generating a race of *curculios* to revel in voracious indolence upon the products of a foreign soil!—*Transactions of the American Medical Association*, 1847.

ROYAL COLLEGE OF SURGEONS.

Gentlemen admitted Members Friday, March 23rd:—Messrs. A. Bowden; H. Cholmeley; G. T. Talbot; J. C. Bompas; J. Dorrian; G. Clarke; J. Pritchard; H. B. Clarke; T. F. Clay; G. J. Brown; J. Wilkins; J. Gibbons.

SOCIETY OF APOTHECARIES.

Gentlemen admitted Licentiates Thursday, March 15th:—Theophilus Taylor, Hereford; John James Williams; William Nicholson Price, Leeds; Thomas Newham, Rothwell, Northamptonshire; John Livy.

Thursday, March 22nd:—George James Thurston, London; William Carrol Satchell, Newport, Isle of Wight; Henry Geary, Atherton, Leicestershire.

OBITUARY.

Died, January 16th, at Queen Camel, Somerset, (where he had resided in the active discharge of his professional duties upwards of sixty years,) Robert Jey, Esq., Surgeon, at the advanced age of 88, much regretted by a large circle of patients and friends.

March 15th, Robt. Abraham Varicas, Esq., M.R.C.S., late of Woburn Place, Russell Square.

March 19th, at Oulart, of malignant fever, caught in the discharge of his duty under the Board of Health, Robert Harvey, Esq., L.R.C.S.I.

March 24th, at Woolwich, aged 70, Dr. Parkin, R.N., of Cawsand, in the county of Cornwall, Inspector of Fleets and Hospitals.

Lately, at Coote Hill, of fever, Muns Walsh, M.D., Medical Attendant of the Fever Hospital and Dispensary.

Lately, at Ilfracombe, Devon, John Sommers Down, M.D., aged 65.

TO CORRESPONDENTS.

Communications have been received from Mr. Bowring; Dr. Davies; Mr. Newnham; Mr. Humphry; Mr. A. Prichard; a Quiet Man; Dr. Holbrook; Mr. Garlick; Mr. Toynbee.

Mr. Parsons' request shall be attended to.

It is requested that all letters and communications be sent to Dr. Streeten, Foregate Street, Worcester. Parcels and books for review may be addressed to the Editor of the Provincial Medical and Surgical Journal, care of Mr. Churchill, Princes Street, Soho.

PROVINCIAL MEDICAL & SURGICAL JOURNAL.

A COURSE OF LECTURES ON SURGERY,

DELIVERED IN THE
MEDICAL SCHOOL OF CAMBRIDGE.

By GEORGE MURRAY HUMPHRY, Esq., Downing
College, Surgeon to Addenbrooke's Hospital.

LECTURE VI.

SUPPURATION; ABSCESS.

Characters of Pus; Essential and Non-Essential constituents; Process of Suppuration, and Formation of Abscess; Nature of Pus Corpuscles, their Number and Regularity of Shape proportionate to the Activity of the Inflammation and Vigor of the patient.—Abscesses may remain stationary, may disappear; Changes in Pus preceding its Absorption; Cases in which Absorption most easily occurs; Mode of Advance of Abscesses to the Surface; Reasons for their generally Bursting Externally; Sometimes Burst into Internal Cavities.—Resistance offered by Fibrous Tissues and Bone; Contrast the Effects of Abscesses and Simple Tumours or Aneurisms; the difference owing to Inflammation attending the former; Diagnosis of Abscesses; Causes of Error.—Treatment of Acute Abscesses; Reasons against too early and too late Incisions; Selection of Spot for Incision.—Fistulæ: Causes and Treatment.

The next product of inflammation we have to consider is pus—a viscid, opaque, creamy fluid, of a white colour, composed of corpuscles floating in the liquor puris, which closely resembles the serum of the blood. If pus be allowed to stand for a short time in a deep vessel, you may witness the separation of these two components; the corpuscles subside towards the bottom, and a thin clear fluid occupies the upper part of the vessel. The essential ingredients of pus are the corpuscles, which vary in size but are generally somewhat larger than those of the blood. They are of spherical, elongated, or oval shape, uneven and granular on the surface, and insoluble in acetic acid or a solution of ammonia. The irregularity of their shape and outline is most marked when the pus is ill formed,—when it is the result of languid inflammation, or when it occurs in delicate scrofulous persons. These corpuscles possess all the usual elements of a cell—viz, a nucleus, cell, wall, and contents. The two former are composed of a modification of fibrin, and the contents of the cell consist of a fluid resembling the serum of the blood; the albumen dissolved in this

fluid may be coagulated by heat, alcohol, &c., and the cell is thereby rendered opaque. The corpuscles are formed according to the ordinary mode of cell development, by the agglomeration of molecules into a nucleus around which the cell wall is produced; and a number of little granular masses may commonly be found in pus, which are probably the elementary cells in their different stages of development.

The essential constituents of pus, then, are corpuscles with peculiar characters, floating in liquor puris, but there are commonly found in addition other ingredients intermixed with these, resulting from the particular locality or the circumstances under which the suppuration has occurred,—such are epithelial cells, fragments of tissues, blood corpuscles, flakes of lymph, and some oil. A peculiar substance named pyine has been described as existing in pus, and was thought by Guterbock to be characteristic of it; but it appears to be often absent in well-formed pus, and occasionally to be present in certain other morbid formations, such as carcinoma, when no suppuration is going on.

The formation of pus is the result of some peculiar change produced in the fibrin of the blood by the inflammatory process, in consequence of which its particles having passed through the walls of the vessels, unite into corpuscles resembling the exudation corpuscles in many respects, but differing from them in the important particular that they are incapable of entering into any higher state of organization, or of acquiring an organic connection with the adjacent living structures. They are, therefore, foreign bodies, and produce precisely the same effects as foreign bodies of any other kind would do under similar circumstances.

The changes in the fibrin which ultimately lead to the formation of pus corpuscles, take place gradually as the inflammation advances in severity, so that we commonly find in the same spot various products indicating the alterations which the fibrin has undergone during the several stages of the inflammation. The fibrin first effused having acquired the properties, on account of which the term coagulable lymph has been applied to it, sets into a soft jelly-like substance in the interstices of the tissues, and renders the part more or less firm or indurated. As the inflammation proceeds, some of the fibrin further altered by the process, becomes converted into pus corpuscles. This usually takes place at the centre of the inflamed part, so that the pus surrounded and walled in by the previously effused and coagulated lymph, forms a cavity in it, and

increasing in quantity stretches this lymph and the surrounding tissues which, blended together, constitute a capsule or sac, containing and isolating the pus. A collection of pus contained in a cavity thus formed, is called an abscess.

With a few exceptions, to be presently mentioned, the suppuration takes place at one spot, and the pus is all contained in one cavity formed at the point where the inflammation is most active. Or if it be not originally contained in one cavity it very soon becomes so, by the softening and absorption or breaking down of the septa, which may intervene between the separate drops first effused. The destruction of these septa, and the formation and enlargement of the cavity caused by the increasing quantity of the pus, is facilitated by the changes induced in the surrounding tissues by the inflammatory process, which predisposes them to yield to interstitial absorption when they become subject to the pressure of the pus.

While the formation of the pus is thus proceeding in the middle of the effused lymph, organization is going on at its circumference. The lymph there situated having been less affected by the inflammatory process becomes converted into tissue supplied with vessels, and constitutes the vascular pyogenic membrane of the abscess. At the same time, the lymph occupying the intermediate position between the circumference of organization and the centre of suppuration, acquires characters intermediate between pus and organized lymph, and forms the soft greyish semi-purulent layer usually found lining the interior of an abscess. Some flakes of it also generally become detached from the vascular membrane and mixed with the pus. The further formation of pus in the cavity of the abscess may depend in part on changes in this soft semi-purulent substance, but it probably results chiefly from the continuance of the effusion of fluid fibrin from the sac into the cavity of the abscess, and its subsequent conversion into pus. This conversion of the newly-effused fibrin into pus is no doubt in some measure determined by the assimilative influence exerted upon it by the already existing pus corpuscles, with which it becomes intermixed in the cavity of the abscess; the fibrin being more amenable to such an influence in consequence of the changes it has undergone in its passage through the vessels and the substance of the pyogenic membrane.

Pus corpuscles have been supposed to consist merely of blood-corpuscles, which have undergone some alteration in size and shape; and certain observers have persuaded themselves that they were fortunate enough to witness the transformation of one into the other under the microscope. This transition, which subsequent investigators have not been sharp-sighted enough to discover, is highly improbable, for the blood globules do not, under ordinary circumstances, transude through the walls of the vessels, and varieties in their shape and size in different animals, are not attended with corresponding varieties in the shape and size of the pus globules. Mr. Gulliver has ascertained that the latter are circular in animals whose blood-globules are oval, and that the size of the one is not much influenced by that of the other.

The notion that pus consists of the disintegrating fragments of tissues broken down by the inflammatory process was exploded before the microscopical examination of the fluid disclosed the distinct organic structure of its constituents. That it is altogether a new formation, and not composed of the detritus of dissolving tissues, is proved by the existence of large abscesses and the discharge of considerable quantities of matter for a great length of time without any perceptible destruction of the adjacent solids.

The only case in which it is at all probable that pus is formed by the solution or disintegration of an existing tissue is that of coagulated lymph or fibrin. We every now and then meet with instances in which masses of fibrin or lymph, both in the large vessels and among the tissues, are to a greater or less extent softened into a fluid which in general characters bears close resemblance to pus, and may practically be regarded as such; but the researches of Mr. Gulliver, detailed in the "*Medico-Chirurgical Transactions*," show that this fluid does not respond to the chemical and microscopical characters of true pus. He finds that the granules and masses of softened lymph, have neither the shape or appearance of pus corpuscles, and they are soluble in acetic acid and a solution of ammonia. There can be no doubt that the induration occurring in the early stages of inflammation generally subsides during the process of suppuration, but we cannot therefore infer with certainty that the coagulated lymph upon which the induration depends, undergoes solution into pus, probably it is absorbed in consequence of the pressure of the accumulating pus upon it.

The thickness of the pus or rather the quantity of the pus corpuscles, is proportionate to the abundance of the fibrin from which they are formed. It is therefore greatest when the inflammation is active and the patient of vigorous constitution; and pus is said to be good, laudable, or healthy, when it is thick and the corpuscles contained in it are numerous and well formed. In delicate subjects whose inflammatory attacks are generally of low languid type, the pus is thin, the corpuscles scanty and ill-formed, many of them not attaining to more than the nucleus stage of development, and others of varying size and irregular shape. Some time ago I opened a chronic abscess in the thigh of a delicate lad. The fluid evacuated was thin, like serum, so that I should scarcely have recognized its nature but for a small quantity of the thicker more purulent matter which flowed when the cyst was nearly empty; a few days after the opening had been made, the abscess became inflamed and a considerable quantity of thick creamy pus issued from the wound; gradually as the inflammation subsided, the pus resumed its thin watery characters, showing the temporary increase of consistence to have been dependent merely on the passing inflammatory attack.

It may occur to you that you have often seen very thick matter evacuated from the chronic abscesses of delicate scrofulous persons, but you have probably remarked that the pus is in such cases curdy, of unequal consistence, and that it owes its thickness, not to the presence of an unusual quantity of corpuscles, but to

the intermixture of flakes and masses of soft, sodden, yellowish, semi-purulent lymph, which are particularly likely to form in these subjects.

Pus possessed of specific qualities presents no peculiarities appreciable by chemical or microscopical observation, which might serve to distinguish it from ordinary pus. We have at present no means of distinguishing wherein consists that subtle essence which makes the pus of the venereal ulcer to differ from that of a common phlegmonous abscess.

I have already said that the corpuscles of pus are incapable of any higher degree of organization—that they are not transformable into any tissue, and do not acquire a nervous or vascular connection with the rest of the body. They may remain for months, and probably for years, without undergoing any particular change; so that it is not safe to decide against the presence of an abscess merely on the ground of the long duration of the swelling. You have seen an abscess removed from the arm of a woman which had existed for more than a year, and another of five years' standing opened in the neck of a man. These are, it is true, exceptional cases, but it is necessary to be aware of their occasional occurrence. In angular curvature of the spine, an abscess not uncommonly remains dormant for a great length of time upon the fore part of the carious vertebræ.

Sometimes pus is absorbed, and the abscess disappears. A series of changes in the contents of the abscess must take place before this result can be accomplished. The liquor puris is first absorbed, the corpuscles remaining for a longer period; gradually these collapse, become broken up and converted into a soft greasy mass, like curded cream or putty, which is seen with the microscope to be composed of small granular molecules, presenting few characters to distinguish them from other dissolving or decomposing organic structures, such as tubercle, cancer, &c.; they may remain in this state for a long time, or, undergoing further liquefaction, they may be completely absorbed. The containing cyst at the same time contracts so as to occasion some puckering of the surrounding soft parts, and is, at length, converted into cellular or fibro-cellular structure.

Apprehensions of the ill effects likely to arise from the presence of pus-corpuscles in the blood owing to the absorption of pus thus effected from the interior of an abscess, are quite groundless, because the corpuscles cannot be absorbed in their entire state; they must undergo solution before these can pass through the lining of the abscess and the walls of the vessels into the circulating current. The innocent qualities of the fluid resulting from their solution is sufficiently proved by the numerous cases in which the contents of abscesses have been absorbed without any injurious consequences.

It now and then happens that the soft greasy contents of an abscess, formed by the partial disintegration of the corpuscles, instead of undergoing further solution, become infiltrated with carbonate and phosphate of lime, and are converted into a mass like mortar or chalk. The sac of the abscess may in like manner become calcified into an earthy crust. Specimens of this kind are occa-

sionally to be met with in the liver, and more frequently in the upper parts of the lungs, and in the absorbent glands of the abdomen and chest. Uneven irregularly-shaped mortar-like masses, which seem to result from calcareous degeneration of abscesses and their contents, are also sometimes found beneath the skin, and in various other parts of the body. They occur most commonly in scrofulous persons, but are by no means always to be regarded as an indication of scrofulous diathesis.

The liquor puris is the ingredient of an abscess which is first and most easily absorbed, and the corpuscles offer the greatest resistance to the process, it being necessary, as a preliminary step, that they should undergo solution; you will, therefore, be prepared to learn, that the spontaneous disappearance of abscesses takes place most frequently when they have been the result of a low degree of inflammation, and in weak delicate persons, because in such cases the liquor puris bears a large proportion to the corpuscles, and the latter are imperfectly constructed, of irregular shape, and often do not pass beyond the nucleus stage of development. The same is probably the explanation of the fact, that pus is more easily absorbed when it is formed in connection with ulcerated bone than under other circumstances, for the subjects of such abscesses are commonly in indifferent health, and the attendant inflammation is often of languid sluggish character.

The termination of an abscess by the absorption of its contents, and the shrivelling up of its sac, is comparatively rare, and scarcely ever occurs when the abscess is the result of acute inflammation. Pus once formed generally acts as a foreign body or irritant, and there is no rest till it has been evacuated; the irritation occasioned by it keeps up the surrounding inflammation, and this leads to the further formation of pus, which, increasing in the cavity of the abscess, enlarges it, distends the lining membrane, and compresses and displaces the adjacent parts. The effect of this pressure upon the surrounding tissues, already softened and disposed to absorption by the inflammation which first occasioned and accompanies the further formation of the pus, is to promote their absorption, and thus make way for the advance of the abscess.

In considering, therefore, the advance of an abscess, and the mode in which it affects the adjacent tissues, there are two chief circumstances to attract our attention:—first, the pressure occasioned by the pus accumulating in the cavity of the abscess; and, secondly, the inflammation attending the formation and progress of the abscess and rendering the surrounding structures more amenable to the effects of the pressure. The combined operation of these two influences sufficiently accounts for the various routes which acute and chronic abscesses in different parts of the body are observed to take, and for their ultimately reaching the surface in the great majority of instances.

The pressure of the increasing fluid contained in the cavity of an abscess is, if we except the influence of gravity, equal in every part of the circumference of the abscess; but its effects are chiefly witnessed in the direction of least resistance, where the structures yielding to it with greatest facility are most easily stretched; for there is some relation between stretching

and absorption, and pressure most easily gives rise to absorption when it is most productive of stretching. Thus, if an abscess occur upon the exterior of the thorax, the pressure of the pus contained in it is equal towards the surface and towards the interior of the body, but on the one side it is resisted by the firm unyielding parietes of the chest; whereas, on the opposite side the integuments and other soft structures being comparatively unsupported yield to it, and are thrown into a curve, so that the abscess acquires a semicircular shape, one side being flat, the other curved or stretched. It is in this latter direction that the effects of the pressure in promoting absorption of the tissues are most observed. A gradual thinning of this outer wall takes place, and proceeds, till at length it gives way or bursts, and suffers the pus to escape; whereas the soft parts, forming the inner wall of the abscess, subjected to an equal amount of pressure, but supported by the parietes of the thorax, and so maintained in their natural position, undergo very little change.

The direction in which the pressure of pus in an abscess is most felt, depends in some measure upon gravity, being greatest at the most depending part; hence an abscess on the fore-part of the lumbar vertebræ, makes its way down in the course of the psoas muscle, where the fine loose cellular tissue offers little resistance, and it usually presents in the thigh.

It generally happens that the outer side of an abscess is, from mechanical causes, the least able to resist the pressure of the accumulating fluid, and this alone is sufficient to account for the fact that the greater number of abscesses burst externally. But another cause operates in producing the same result, which is the greater disposition to inflammation evinced by the tissues lying on the superficial, than by those on the deep side of the abscess. This circumstance, noticed by John Hunter, and supposed by him to depend on a law of nature comparable with that by which vegetables approach the surface of the earth, renders the superficial textures less capable of resistance, softens them, and makes them a more easy prey to absorption. It is chiefly observable in acute abscesses, and, together with the sudden stretching to which the parts are subjected in consequence of the quick formation of pus, accounts for the rapidity with which they find their way to the surface, and also for the well-known fact, that abscesses situated deeply, in close contact it may be with internal cavities, do generally approach the surface of the body, and burst in that direction.

The liability of serous cavities to the discharge of pus into them, is further diminished by the disposition of their lining membranes to the effusion of lymph, which agglutinates their surfaces, and protects their cavities; nevertheless the event occasionally takes place. Abscesses have descended from the upper part of the neck in the loose tissue which surrounds the great vessels, and have burst into the pleural cavity; and they have occasionally made their way into the peritoneal sac from the liver, and from beneath the abdominal muscles. The cavities of the joints may suffer in the same manner. A psoas abscess sometimes passes through the bursa on the under surface of the tendon

of that muscle into the hip-joint; and an abscess beneath the quadriceps muscle in the thigh may find its way into the synovial cavity of the knee.

The textures around an abscess usually undergo absorption with readiness proportionate to the facility with which they yield to the pressure, and proportionate also to their vascularity and liability to inflammation. Thus fibrous tissues offer far more resistance to the progress of an abscess than muscles; and nerves and vessels often remain as prominent ridges or bands crossing the interior of an abscess. Bone, though offering great mechanical resistance, and by its support preventing the yielding and absorption of the textures intervening between it and the abscess, easily undergoes absorption when it is itself subject to the immediate influence of pressure. Hence the pus in an inflamed joint attended with destruction of the cartilages not unfrequently bores through the articular end of the bone, and makes its way into the medullary cavity of the shaft. The comparative facility with which absorption of bone may be induced, is well illustrated by specimens of aortic aneurisms, which by their pressure destroy the bodies of the vertebræ, but leave the intervertebral fibro-cartilages standing out in relief between them. Again, a fibrous tumour situated on the outside of the dura mater will make its way through the skull by inducing absorption of the bone, whereas if it grow from the interior of that membrane, it will project in the opposite direction, and, causing absorption of the cerebral convolutions, will become imbedded in the brain.

The attendant inflammation gives rise to the difference of the effects of abscesses, and of simple cysts or tumours upon the surrounding parts; the latter produce a mere mechanical impression, and the direction which they take depends solely upon the greater or less resistance of adjacent tissues. A fibrous tumour of the uterus, for instance, stretches the uterine tissue which becomes expanded over it, and it projects either into the abdominal cavity, or into the interior of the uterus, according as it happens to be situated near to the outer or the inner side of the wall of the organ. In either case it may become pendulous or polypous, and it does not commonly acquire adhesions to the surrounding parts. The progress of aneurisms is an illustration of the same point. The direction they take is regulated simply by the mechanical influence of the pressure of the blood in their interior, and the resistance offered by the surrounding parts, so that they burst, as an ordinary occurrence, into the adjacent serous cavities, or even into the loose cellular tissue which may happen to surround them. That such results rarely occur in the case of abscesses is, no doubt, owing to the accompanying inflammation, which by its adhesive effects unites the adjacent tissues, and seals up the internal cavities, and by its softening influences disposes the tissues to yield, and renders them more liable to absorption.

The symptoms of an abscess are in most instances sufficiently clear. The occurrence of a soft spot in the midst of an indurated inflammatory swelling, is a pretty sure sign of the formation of matter. The integuments over the soft spot generally become livid, and bulge in consequence of the pressure of the pus, and

the abscess is then said to point. When the fluid has accumulated in any considerable quantity, we may distinguish fluctuation by placing a finger upon one part, and suddenly pressing upon another.

There are, however, some circumstances which are likely to mislead, unless we be careful how we arrive at a decision, from the observation of this latter symptom. An effusion of serum caused by inflammation in a part where the tissue is loose, as in the back of the head, communicates to the finger an impression which is very likely to be mistaken for the fluctuation of fluid in a cavity. This source of error may sometimes be guarded against by carefully expressing the serum with the fingers before we attempt to ascertain the presence of fluctuation; but when the part is very tender, this cannot be done. A tumour of soft elastic structure, a moveable tumour, or an enlarged gland slipping under the skin, may all impart an impression resembling that of fluctuation. You will avoid many mistakes by following the rule of not deciding as to the sense of fluctuation with the fingers placed in a line transverse to the axis of a limb, for the muscles are easily displaced in that direction, and the impulse so occasioned may be mistaken for fluctuation. You may readily convince yourselves of this source of error by examining your own thigh, with the fingers placed as I have mentioned. If you then alter the position of the fingers, and place them one above the other in the long axis of the limb, you will be immediately sensible of the importance of attending to this simple rule.

The surgeon sometimes infers the presence of deep-seated matter, from the red or dusky colour, and the peculiar appearance of the skin, and indurated or oedematous condition of the superficial parts. This is more particularly the case in the perineum, and an incision under such circumstances frequently proves the correctness of the diagnosis, although no fluctuation may be felt.

We may suspect the formation of an abscess in the hinder part of the abdomen, or some other deep situation, when a patient who has been for some time ill, without presenting the well marked symptoms of any particular malady, begins to suffer repeated chills, followed by perspirations, occurring at irregular periods, and without any obvious cause.

The diagnosis of abscesses in different situations, from aneurisms, hernia, malignant tumours, and the like, I must leave to your own observation, advising you to take every opportunity of instructing yourselves in this very important department of practical study. Very little observation will assure you of its difficulty, and very much experience will be required to surmount it.

I must, in addition, add a word of caution regarding chronic abscess. Let the numerous mistakes with respect to them which have occurred in the practice of the most experienced surgeons warn you not to presume too much upon your own powers of discernment. They occasionally resemble adipose and other tumours so closely, that I am not acquainted with any signs by which they can with certainty be distinguished from them. The history, symptoms, and physical characters, are sometimes so precisely like those of a solid tumour, that I do not believe it possible,

in some cases, to form a diagnosis, without having recourse to the grooved needle. Some of you will remember the case of a woman who had a firm knotty tumour upon the muscles on the outside of the forearm, which presented all the usual characters of a solid tumour. It had been first observed when about as large as a pea, a year before we saw the case, and it had gradually increased in size, without pain. Its unusual situation for an adipose tumour, and the knowledge of our liability to errors of diagnosis in these cases, induced me to puncture it with a grooved needle before attempting its removal, when a drop of pus declared its nature, to the surprise of every one who had examined it.

I used to think the lobulated margin of a tumour, when present, to be a tolerably sure sign of its solid or adipose nature, but I have several times felt the irregular knotty induration around a chronic abscess so closely resembling the lobulated edge of a fatty tumour, that this symptom is certainly not to be relied on as a diagnostic feature. I can only advise you to be cautious in these doubtful cases, and not to despise the use of the grooved needle, which may occasionally save you from the annoying exposure of having removed an abscess under the impression that you were operating upon a solid tumour, and prevent your attempting an operation, which the adhesions of the abscess might render you unable to accomplish.

In the treatment of acute abscesses, our object is to effect the evacuation of the pus as quickly, and with as little mutilation of the body, as possible; in such a manner, too, as may best favour the subsidence of the inflammation, and the healing of the wound occasioned by the discharge of the pus. As soon as there is evidence of the presence of matter, we discontinue the measures intended to prevent its formation, and commonly apply a poultice, which, by its warmth and moisture, certainly has the effect of relieving the pain; and it probably also, to a certain extent, promotes suppuration, and facilitates the advance of the abscess to the surface, by softening the superficial parts, and causing them to yield more easily to the pressure of the pus.

I am not disposed to agree with those modern surgeons who would discard poultices as useless and filthy encumbrances. Neither water-dressing, spongipiline, or any of the new-fashioned substitutes (advantageous as they may be in some cases,) will adapt themselves so nicely to the surface, and afford so soft and comfortable an application to a tender and suppurating part, as a well-made poultice, which has the effect of assuaging the surrounding inflammation, while it facilitates the advance of the matter to the surface.

Then, with regard to the propriety of opening abscesses in various circumstances, you will find much difference of opinion. We will first consider the case of a simple acute abscess, without reference to its situation. I believe, *ceteris paribus*, that it is the better plan to leave such an abscess to take its course till it has approached very near to the surface, for two chief reasons; first, because the formation of matter seems to be in some way or other a relief to the inflammation, which usually becomes more limited in its extent as

soon as suppuration commences; and in the course of the suppuration, the induration which preceded it becomes greatly diminished, either from the absorption of the effused lymph caused by the pressure of the accumulating pus upon it, or in consequence of its undergoing solution, and becoming mingled with the contents of the abscess. There can, I think, be no doubt, that if an abscess be opened early, the process of suppuration does not proceed so freely, the inflammation and induration remain longer, and the healing of the wound is more slowly accomplished. For the same reason, if, in the case of inflamed glands, as bubo, the pus formed at one spot be too early evacuated, the swelling and induration of the surrounding glands is more tedious, and there is greater liability to the occurrence of successive suppurations in them, than if the primary abscess be permitted to form well, and be opened later, or allowed to burst spontaneously. I believe that this remark may be applied in like manner to the treatment of boils, and that I am correct in saying, not only that the first boil will heal more quickly, but that the chance of the occurrence of others is lessened, if it be allowed to suppurate fairly, and to burst spontaneously.

Secondly. The natural advance of an abscess to the surface, by the extension and thinning of the superjacent structures, is such as to afford an easy and direct exit to the pus when it bursts; whereas, if an opening be made into a deep abscess, through the thick covering of soft parts, the artificial channel is long, is narrow in its whole length, is very likely to become obstructed, and the discharge of the pus being consequently impeded, the contraction and healing of the abscess is slow and difficult.

As a general rule, therefore, it may be stated, that an abscess will discharge its contents more easily, and will close better, if it be allowed to burst, or be not opened till it has approached the skin. I make this limitation, because a timely incision through the skin will often prevent extensive undermining and destruction of integuments, or the formation of sinuses, enduring for months, requiring, perhaps, painful incisions for their cure, and followed by ugly sores. I wish to be clearly understood upon this point, for though I object to the opening of deep abscesses, unless some particular circumstances render it desirable, I am fully sensible of the great advantages that are often gained by incisions through the integuments, before they have become much thinned, discoloured, or otherwise altered by inflammation. The bad results of too long delay in opening abscesses are in no cases more apparent than in buboes. I am certain that the troublesome sinuses we are so often called upon to treat as a consequence of buboes, might, in by far the greater number of cases, be prevented by a timely incision through the integuments, before they have become undermined, and their vitality has in consequence been impaired. You have need to beware, therefore, in avoiding the error of opening an abscess too early, that you do not fall into the opposite extreme of delaying the incision too late.

I have intimated that particular circumstances may exist which would induce us to deviate from the rule

of leaving an abscess to approach the surface. Such are severe pains occasioned by the pressure of the pus, or injury to important parts likely to result during the time required for the progress of the abscess to the surface in the natural manner. A man may die from the pressure of an abscess upon his trachea before the legitimate period for opening has arrived. An abscess situated in loose cellular tissue, as in the axilla, or about the rectum, will be likely to burrow about and leave extensive troublesome sinuses, unless it be opened early; or an abscess may be so deep, and covered by structures of such density, that it cannot easily make its way to the surface, and may, in consequence, spread from one part of a limb to another, and may even burst into an internal cavity, the pleural, peritoneal, or the knee joint.

There are, besides, many cases in which the presence of the pus evidently exerts a powerful irritating influence maintaining and causing an extension of the inflammation. This happens more particularly when the pus has any peculiar qualities, as in the case of a poisoned wound, or when it is the result of very acute inflammation; or where its formation is not preceded by the adhesive stage of inflammation, and it therefore spreads from cell to cell of the areolar tissue, as in phlegmonous erysipelas; where it is situated among dense unyielding textures, as in the palm of the hand, or in textures richly supplied with blood-vessels and nerves. In all these cases, and in others of like kind, the importance of early incisions (of incisions made as soon as there is any evidence of the presence of matter) cannot be too strongly enforced, and the good effect of the free evacuation of pus will be apparent from the immediate subsidence of the surrounding inflammation.

Having determined on opening an abscess, you will do well to select for your incision the spot at which there is a disposition to point, if any such be shown, because the pus will escape in this situation more easily than in any other, and the textures intervening between the abscess and the surface are probably thinner there than in other parts. If this be a depending spot, so much the better; if it be not, I would be unwilling to neglect the hint which nature gives as to the point of selection, for the mere sake of securing a depending opening; for, if you do this, the abscess will probably burst after all at the pointing spot, and the free discharge of its contents will not take place till it has done so. I remember a lad who was suffering very severe pain from a large deep-seated acute abscess in the thigh, which was just beginning to point on the inside of the limb above the knee-joint. It being thought advisable to open the abscess on account of its proximity to the joint, and the great distress occasioned by it, an incision was made on the outside of the thigh for fear of injuring the femoral vessels. The incision seemed to be sufficiently free, and a considerable quantity of pus escaped, but it did not continue to flow freely through the wound; it collected again in the cavity of the abscess, and the lad obtained very little relief till a few days afterwards, when the abscess burst at the spot where it had begun to point, and a free discharge of matter ensued, affording immediate and permanent ease.

The incision into an abscess should be free, taking such direction as least endangers the superficial vessels and nerves which generally run parallel to the long axis of the limb, and the pus should be allowed to flow in a continuous stream through the wound as it is expressed by the contraction of the sides of the abscess. The orifice is thus kept open, and the re-union of its edges prevented. If the matter be all squeezed out when the opening is first made, its further flow is of course suspended till it has reaccumulated to a certain extent in the cavity of the abscess, and in the meantime, the edges of the incision falling into contact, are likely to unite together, and a second incision may be needed.

The application of *potassa fusa* as a means of opening an abscess, should only be resorted to when the case has been neglected too long, and the integuments have become so undermined, that they are not likely to heal if the matter be evacuated in the ordinary manner.

When the opening, natural or artificial, has been made, the formation and discharge of pus continues for a certain period, the surrounding induration gradually disappears, the cavity of the abscess is diminished by the contraction of its walls, which ultimately come into contact, and adhere together, healing like any other wound. The lymph of which they are composed continues to contract, and the only trace of the abscess at last remaining may be a mere puckering of the surrounding structures around a more or less opaque star-like cicatrix.

Many circumstances may occur to interfere with this speedy healing of the abscess. Not unfrequently the apposition and union of its walls are prevented by the formation and discharge of pus, which may be maintained for a long period by a piece of carious bone or a diseased gland at the further end of it; or, there may be a flow through it of some secretion, (the urine, tears, or saliva,) consequent on a communication which has taken place with the duct of a gland. The track of an abscess thus kept open is called a sinus or fistula, and the lining membrane in course of time assumes a firm texture, with smooth surface like that of a mucous membrane in which the healing processes are not very easily excited, although the cause of the persistence of the fistula be removed. One of the most common causes of the continuance of a sinus is the undermined blue or livid condition of the integuments covering it, which show more disposition to ulcerate or mortify than to assist in carrying on the healing processes, and such sinuses will remain for months, unless the integuments be divided or destroyed and the canal reduced to an ulcer, from the margins of which cicatrization may proceed in the usual manner.

The closure of an abscess may fail to take place in consequence of great languor and inactivity of the healing processes, which is likely to happen in the case of chronic abscesses and in delicate scrofulous persons, or when the walls of an old abscess have become thick and indurated so that their contraction and the closure of the cavity occurs only in a partial manner. Fistulæ resulting from the former of these causes may be sometimes induced to heal by measures tending to

invigorate the system, and by local stimulating applications. The indurated callous fistulæ remaining after the opening of old abscesses, are most easily remedied by extirpation with the knife, or caustic, if that can be done.

The continual free movements to which the parts are subjected are the cause of the persistence of fistula in the loose tissue of the axilla, ham, and the neighbourhood of the anus. I believe that fistulæ, occurring in the latter situation, generally originate in abscesses formed on the outside of the rectum, and that the communication with the bowel takes place after the abscess has burst externally. More rarely the abscess bursts into the rectum, and the blind fistula, as it is called, so formed, subsequently makes its way externally. In the greater number of recent fistulæ opening beside the anus, no communication with the bowel exists; but in the majority of fistulæ of long standing, an opening into the rectum will be found at some point or other, generally near the upper margin of the internal sphincter. I am aware that these remarks do not quite accord with the statements of some surgical authorities of very high reputation, but they are made after the examination of a considerable number of cases, the records of which I have for the most part preserved. The treatment in these cases corresponds with that of subcutaneous fistulæ, the only difference being that the sinuses are laid open into the bowel in the one case, and the integuments are divided in the other.

CLINICAL LECTURE ON ALBUMINURIA.*

DELIVERED IN THE

LEEDS PUBLIC DISPENSARY.

By J. D. HEATON, M.D., Senior Physician to the Dispensary.

Thomas Stockdale, aged 20, a shoemaker, of middle stature, leuco-phlegmatic complexion, rather stoutly made, and of regular habits. He caught cold a fortnight before admission, from wearing wet shoes, after which he felt pains all over, and in the back, and began to swell.

May 29th. I first saw him this day, and found him generally anasarctic; much pain in the loins, especially in an afternoon; urine scanty, of a cherry-red colour, depositing a red precipitate of the colour of blood, alkaline, and very albuminous; tongue white, red at the tip; pulse 90, full, rather sharp. He was ordered to be bled to eight ounces, and afterwards to have a warm bath.

R. Inf. Diosmæ, oz. viij.; Tinct. Digitalis, dr. iss. M. Sumat, oz. j., ter die. R. Pulv. Ipecac. Co., gr. x.; Hydrarg. Chloridi, gr. ij. M. Fiat pulvis omni nocte sumendus. Omni mane sumat Potassæ Bitart., dr. ij.

31st. Unfortunately the blood was not kept, so that its appearance cannot be noted. He perspired a good deal after the bath, but rested ill during the night.

Yesterday he had much pain in the loins, especially on the left side. This morning he feels better; the body is less swelled; he has less pain; he makes more water, which is less bloody; the tongue appears as before; the bowels have been freely opened; pulse 30, full. Ordered to be cupped in the loins, to have a warm bath each evening, and to continue the medicines.

June 1st. There has been no pain in the back since he was cupped; he is less dropsical; the urine is more abundant, and paler, still muddy, and depositing a red sediment; slightly alkaline; highly charged with albumen, though less so than when first examined. The tongue is no cleaner, but the pulse is less full.

June 5th. Since last report he has been visited by one of the resident officers of the Dispensary, and the mixture changed for a stimulating diuretic, containing compound spirits of juniper, and tincture of squills. He has made more water, and is less swollen, and has had no pain in the loins, but the urine is more highly coloured, of a dirty red, and very thick. He had a restless night; the pulse is rather frequent; gums slightly affected with the mercurial; bowels freely opened. To continue the cream of tartar each morning, and the Dover's powder at night, but without the calomel. *Addē misturæ Liq. Potassæ, dr. iss.* From this time he gradually improved.

June 26th. To day he came to the Dispensary. He considers himself almost well. There is no œdema, except slightly about the ankles; he has no pain in the loins, or elsewhere; his strength and appetite are returning; pulse natural; tongue still rather white. Urine has a natural appearance, but still slightly clouded, on the addition of nitric acid.

July 17th. Wishes to be discharged, as he feels quite well. There is no œdema; the urine is of average quantity, specific gravity 1012, very slightly clouded by nitric acid.—Discharged.

After being discharged from the books I had still opportunities of occasionally seeing this man. I ascertained that the urine returned to a perfectly natural state, and he has continued in health up to the present time. In anticipation of this lecture I have had the urine tested, and it is now quite natural and free from albumen.

I shall next give a brief sketch of a case of acute albuminuria, which terminated fatally. It did not fall under my treatment, nor occur in this institution, but in University College, London, some years ago now, when I was clinical clerk there, and was reported by myself, in the *Medical Gazette*, more at large, with several other cases of albuminuria, which were treated in the same hospital. I mention it here as being a good instance of this form of disease.

Joseph Wilson, admitted June 7th, a house-painter, aged 45, married, of regular habits; general health has been good. About a month since he caught cold, and was laid up for a few days. When recovering from this, a day or two after he had returned to his work, his feet began to swell, and the scrotum and penis became much distended with fluid. The swelling increased, so that he was unable to work, and he

became very weak and languid, but without pain. The urine was more scanty than usual, high-coloured, but, he says, not turbid. He had medical advice, and took very strong purgatives, and was afterwards salivated, but the swelling only increased. Whilst under the action of mercury, he again caught a severe cold, which caused dyspnoea and cough, with much expectoration, the sputa being streaked with blood, though he has not had symptoms of pulmonary disease at any time previously. Two days before admission he was seized with a sharp pain, shooting from the right shoulder to the sternum.

At present the whole body is anasarcaous; the respiration is short and hurried; he has some dyspnoea and cough, but not very troublesome; decubitus on the right side; the pain in the right side of the chest continues; it is increased by cough, or a deep respiration; tongue brown, with a tendency to dryness; gums mercurialized; bowels relaxed; no tenderness of the abdomen; pulse small and frequent; urine scanty, turbid, high-coloured, very albuminous, specific gravity, 1032. Physical examination of the chest detects a considerable quantity of fluid in the right side, (there being complete dullness of stroke-sound up to a level varying with the position of the patient, and ægophony at the inferior angle of the right scapula,) which presents very slight respiratory movements, respiration being carried on chiefly by the left side. Sounds of the heart natural.

Lateri dextro appl. Empl. Cantharidis. R. Pil. Hydrarg., gr. iij.; Ext. Hyoscyami, gr. ij; Pulv. Scillæ, gr. j. M. Fiat pil. ter die sumenda. Bibat potum Potas. Bitartr. ad libitum.

8th. No great change in the symptoms. Cont. Pil. R. Tinct. Cantharidis, m. x.; Liq. Potas., m. xx.; Sp. Æther. Nit., dr. j.; Mist. Camph., oz. j. M. Fiat haust. ter die sumendus.

10th. The patient seems worse; severe pain down the right side of the chest and abdomen, increased by any movement; respiration short and frequent, chiefly abdominal; thirst; anorexia; much diarrhoea; tongue brown and adhesive; urine as before; not above three to four ounces passed in the twenty-four hours. Pulse 100, small and feeble. Fiat venesectio ad oz. xij. sang. Foventur abdomen.

11th. The quantity of blood ordered was obtained with difficulty; coagulum moderately firm, but neither cupped nor buffed. The patient feels better; the pain is relieved; tongue rather moist; diarrhoea continues; urine not increased in quantity. In the afternoon a friction-sound was heard under the right clavicle, where he had more pain, and the pulse became sharp and more frequent. Parti dolenti admov. Hirudines xij.; Auge Tinct. Cantharidis ad m. xv.

12th. The symptoms as before, but aggravated; no increase in the quantity of urine. R. Decocti. Scoparii Co., oz. iv.; Potas. Nitrat., gr. x.; Sp. Æther. Nitr., dr. j.; Sodæ Sesqui-Carb., gr. x. M. Fat haust, ter die sumendus.

15th. Has seemed better the last two days; the pain is much relieved; he can lie on the right side without uneasiness, and prefers this, as the respiration is then

easier; cough troublesome; the sputa have the rusty tint of pneumonia, but no crepitation has been detected in the chest; tongue moist; pulse rather less feeble; but the urine is scarcely increased in quantity; the diarrhoea continues. R. Pulv. Antimon., gr. iij.; Pulv. Ipecac. Co., gr. vj. M. Fiat pulvis omni nocte sumendus.

18th. No very marked change in the symptoms; there seems increasing prostration, but he thinks himself no worse; the diarrhoea is abated; the urine is more dark coloured, and not increased in quantity, specific gravity 1021; the right side of the chest is still distended with fluid. E lateri dextro capt sang., oz. viij., ope c. c.

19th. Increasing debility; voice whispering; mind confused; drowsiness, but no sleep; no headache; stools passed involuntarily; great oedema of all parts of the surface; the wound of venesection in the arm has never healed, it is now an open, unhealthy-looking ulcer; urine not increased in quantity, very dark-coloured, no precipitate on boiling, but copious flakes of albumen precipitated on adding nitric acid. Adde Haust. Potas. Acetatis, dr. ss.

21st. Tongue dry and brown; pulse 120, scarcely perceptible; stools and urine passed involuntarily; mind confused. He died in the evening.

A *post-mortem* examination was made fifteen hours after death. On opening the thorax a large quantity of serum, three or four pints, was discharged, containing flakes of yellowish, opaque lymph; this fluid was chiefly contained in the right cavity of the chest, but partly also in the left. The surfaces of the pleura exhibited much inflammatory vascularity, and were covered with similar flakes; and there were recent soft adhesions between the diaphragm and the right lung. The right lung contained miliary granulations scattered throughout its substance, but chiefly in the upper lobe; its whole substance was congested, more solid, and less crepitant than natural. The lower lobe was the seat of lobular inflammation, in distinctly circumscribed patches, which were completely carnified, and of a florid red colour, the rest of the lung presenting a dark purple colour, on the surface of a section. The left lung had some old adhesions posteriorly to the walls of the chest: it was much congested, soft, and lacerable, but crepitant throughout; there was a small tubercular cavity in the upper lobe, which was of old standing, and had its walls contracted. The lining membrane of the bronchial tubes in both lungs presented considerable vascular injection; and in the right lung the longitudinal fibres of the tubes were remarkably hypertrophied. The heart was healthy. A considerable amount of clear serum was contained in the pericardium. The right kidney was larger than natural, soft and flabby; on stripping off the capsule, portions of the substance of the kidney tore off with it; the surface was then seen of a faded, brownish-yellow colour, with here and there patches of a lighter colour, which, on laying open the kidney, were seen to extend through the thickness of the cortical structure. The whole substance of the kidney was of the same pale colour; the section of the cortical substance was finely granulated, and was

variegated with star-like spots, of bright red vascularity. This kidney weighed five ounces and a half. The left kidney was considerably larger than the right, and more soft and lacerable; it had the same colour as the right kidney, and was similarly interspersed with albuminous patches; the granulations were larger, and extended more deeply, and the spots of vascularity were more marked. It weighed seven ounces. The other abdominal organs presented no very marked appearances. The peritoneal cavity contained a considerable amount of clear serum.

In the case of Stockdale, we have an acute attack apparently unprecedented by any previous disease of the kidneys. Cases of this kind are frequently called inflammatory dropsy, but their connection with disease of the kidney, and a consequently albuminous state of the urine, is now fully recognized. They much resemble those cases of anasarca occurring after scarlatina, usually from too early an exposure to cold, and of which most epidemics of this latter disorder furnish us with several examples, especially those which occur during a cold bleak condition of the atmosphere. Although this is a very serious affection, and may terminate fatally, either in the acute stage, as we shall see in the next case, or more tardily by passing into a chronic state, yet, as there was no reason in this instance for supposing the structure of the kidney to be as yet materially deteriorated, the prognosis was in this respect more favourable.

The case was ushered in by the usual symptoms of inflammatory fever, and then the body began to swell. Frequently the dropsy appears in the upper parts of the body, and in the face, as clearly as in other parts, and this circumstance alone might lead us to suspect the true nature of the dropsy. The serous effusion in such cases as we are considering, depends upon some changed condition of the blood and of the circulation, affecting the whole body; the cutaneous perspiration has been, perhaps suddenly, arrested from exposure to cold; this of itself allows more water than is right to accumulate in the blood, and, as at the same time, the kidneys become congested,—the effect of the same exposure being to cause the blood to accumulate in internal organs,—they take on a diseased action, and become incapable of secreting the proper amount of urine; from *this* cause, likewise, the blood-vessels become the more distended, and, with the accompanying fever, the heart's action is increased, forcing the blood more powerfully into the already over-charged vessels, which, thus subjected to such undue pressure, at length allow the watery parts to exude through their coats, and the cellular tissue of all parts, even the more elevated, as the face, in which it is most apparent, becomes suddenly infiltrated. But where serous effusions depend upon more local causes, as mechanical obstructions to the circulation, or are merely of a passive nature, as when consequent upon a thin, watery, state of the blood, but without any general plethora of the vessels, the oedema is more local, or appears first in more depending situations, where the hydrostatic pressure of the blood upon the vessels is greatest, and to which, likewise, the

serous exudation naturally tends to gravitate through the cellular tissue. In the acute form, likewise, the dropsical parts often have a tense feel, and will not readily *pit*, for the cellular tissue having become more suddenly distended, does not immediately accustom itself to yield, and allow the serum to escape and pass easily through its areolæ when subjected to pressure.

Whenever the symptom of dropsy presents itself, we are led to make an early enquiry into the condition of the urine; and in such cases as we are considering, we shall find it presenting the characters which have been stated in the report. Any considerable reduction in the quantity of the urine will render it turbid with a deposit of lithate of ammonia, which, being not very soluble, the reduced quantity of the watery solvent cannot now retain in solution. This precipitate is itself more or less pink in most cases, being in combination with a colouring matter contained in the urine; but when the vessels of the kidney are much distended with blood, not merely the serous part of the blood may pass into the urine, rendering it albuminous, but some of the red particles, likewise, giving a more decidedly red colour to the urine, in which they may be detected under the microscope. Such urine may be either alkaline as it is voided, or may speedily pass into an alkaline state, from the conversion of the urea into carbonate of ammonia; but in *chronic* cases of this disease, when the aqueous constituent of the urine is passed in excessive quantities, but of a very low specific gravity, and containing little urea or other animal principles, it decomposes slowly, so that any slight acidity it originally possesses is long retained. It should be borne in mind that an alkaline state of the urine interferes with one of the ordinary tests for albumen, preventing that principle from coagulating by heat; the urine should therefore be tested likewise with nitric acid. Occasionally we find urine which, when boiled, acquires an opalescence which is not removed on adding any mineral acid, which therefore cannot be occasioned by a phosphatic deposit, but in which nitric acid produces no change; this is probably occasioned by some protein compound similar to albumen, and affording similar pathological indications, but differing from the chemical characters of albumen in this respect. Perhaps a solution of bichloride of mercury is the most certain test for albumen, or its modifications, but it is more liable to fallacy than the other two I have mentioned, as it will occasion precipitates with other principles besides albumen which the urine may contain. Another caution in testing for albumen, which I think may sometimes be of value, is, that when the quantity of albumen is small, if the urine be allowed to become old before it is tested, it may become so far decomposed as no longer to answer the tests for albumen, though it might have given decided indications if examined when fresh. Probably some of the instances, where one test will produce the characteristic effect, though another fails, may be explained in this way.

The treatment was similar to that of the former cases, but here more active, corresponding with the greater activity and urgency of the symptoms. The state of the general circulation, together with local

symptoms of hyperæmia in the kidneys warranted a moderate bleeding in the arm, followed by cupping to the loins. If this depleting treatment produces its desired effect, we soon see the result in the urine, which becomes more copious and less albuminous; but I am opposed to very profuse bleeding in this complaint, for it must be borne in mind that there is some defect in the blood, which is shown by the deposit of lymph of a bad quality in the kidneys, and the loss of much blood will still further weaken and deteriorate its quality. In addition to this, some of the more sedative, and less stimulating diuretics were ordered, and the bowels were acted on. It is important likewise to promote a free cutaneous secretion, which is usually very deficient in this complaint, by which we shall further derive from the more deeply-seated vessels to the surface, and so still further relieve the congestion of internal organs. For this purpose warm baths are very serviceable, together with other sudorific treatment. Dover's powders combined with calomel was prescribed for this purpose. I gave mercury in this case merely as an antiphlogistic, and to counteract the constringing effect of the opium. For the same reason that I should think it desirable to bleed largely, I should think it injurious to bring the system fully under the influence of mercury. I feel sure that in some cases where I have seen mercury given freely and for a considerable time, the disease has been aggravated, and the fatal termination brought on more speedily by this treatment. I think this was very probably so with respect to Wilson, the next case, who had been salivated before admission to the hospital, by which, probably, the progress of the disease was accelerated.

In respect of diet, besides the propriety of the antiphlogistic regimen in these cases, as indicated by the febrile and inflammatory symptoms, perhaps a farinaceous diet may be preferable to any animal food during the imperfect excretion of the urinary principles by the kidneys, as being less favourable to the free formation of those nitrogenous compounds; this, however, could only act indirectly, as we do not suppose these excrementitious matters to be formed in the blood from the food, but by the conversion of the effete tissues.

By these methods which I have specified, the improvement was quite satisfactory; the pain in the loins and the fever subsided, the urine assumed a more natural character, and the serous effusion was gradually reabsorbed. I think some more tonic treatment was adopted subsequently, though I have not the particulars of this. The patient was dismissed sooner than was quite prudent, by his own wish. Fortunately no bad consequences followed: and that the cure is complete and permanent is satisfactorily shown by the long time (three years) of continued good health, which he has since experienced, and by the urine being, as I have ascertained, in a perfectly normal state at the present time. But even where the recovery is so complete as in this case, probably some predisposition is left to the disease, to which any neglect of proper hygienic precautions may add the exciting cause. Any bad lymph which has been deposited in the tissue of the kidneys before the arrest of the disease, must

remain, and may probably be incapable of gradual removal by the absorbents; in proportion as lymph is less unhealthy—less organizable, is it less capable of reabsorption. This may remain in a quiescent state, and the kidneys may retain a sufficient amount of healthy structure to perform efficiently their proper function. But this morbid deposit must give a proclivity to a return of the condition by which it was produced, both by interfering with the uniform and regular circulation in the part, and so favouring local congestion, and by acting as a nucleus around which fresh morbid deposit of like nature might be then aggregated.

I have taken the last of the cases which I read to you, because it gives a better instance of the fatal termination and *post-mortem* appearances of acute albuminuria than any I could find in our own reports. As the case was not under my own care I shall make no observations on the treatment, especially as the former cases have afforded opportunities for noticing that which I find most successful, and the principles upon which it is founded. The attack seems to have commenced with exposure to cold. At the time of his admission, the symptoms of the albuminuria were similar to what we have seen in the former case; but there were also those of bronchitis, which from the appearance of the blood in the sputa might be supposed to be connected with tubercles, but the effusion of serum into the chest must have so far altered both the character and the signification of the physical signs, that this opinion might not be capable of exact confirmation. The fluid detected in the right side of the chest might have been supposed to be merely a part of the general anasarca; but the pain which accompanied it seemed inflammatory, and on a subsequent examination, a friction sound was heard at one point; besides which, a mere dropsical effusion would not have been confined to one side of the chest as was this. These inflammations in the chest refused to yield to the treatment, nor could the function of the kidney be restored. The urine did not increase in quantity; it was only from three ounces to four ounces per diem; whereas, the average quantity of health is upwards of two pints. And in this small amount of fluid, even though of a density above the healthy standard, being 1032, instead of about 1020, it is evident much less than the natural amount of the principles proper to the urine must be excreted from the blood. These, therefore, must have accumulated in the blood, where, if retained, they prove as poisonous as other noxious principles might if introduced from without. When the system is suddenly subjected to this injurious influence, as by an acute attack, it suffers much more, and more speedily, than when the poison more slowly accumulates in the chronic form of the disease; for in the latter we frequently find the urine for a length of time to be voided having a specific gravity little above that of pure water, which must leave the blood in a very impure state; and yet such patients having been gradually habituated to this condition, suffer no very urgent inconvenience. The same is true with respect to other excretions: if the respiration of a healthy man

be suddenly obstructed by an attack of asthma, or by acute laryngitis, he suffers most distressing dyspnoea, or dies asphyxiated—poisoned by carbon retained in the blood; but he may become habituated to a serious diminution of the respiratory function by chronic emphysema, with much less inconvenience. So, again, with regard to the secretion of the liver; a sudden suppression of bile causes speedy death with comatose symptoms; but there are instances where the common biliary duct has been permanently closed for a length of time, and the secreting structure of the liver atrophied, and yet the patient has not been poisoned by bile, but died gradually of inanition. Dr. Budd relates an interesting case of this kind in his work on diseases of the liver.

To the unhealthy condition of the blood we must attribute the low form of the inflammation occurring in the chest, lingering on without very active symptoms, and yet not amenable to treatment; and to the same cause, its inability to pour out healthy lymph to heal the small wound caused by the lancet, which, consequently, degenerated into an unhealthy sore.

No means that were used succeeded in arousing the kidneys to a more efficient performance of their function; they only became more inactive, although the quantity of urine, by measure, was not increased, the specific gravity fell, shewing that less and less of the essential constituents of the urine was separated from the blood. Had the suppression been somewhat more complete, it would have constituted a case of ischuria renalis, or suppression of urine, where death is speedily inflicted by the poison of the urinary principles retained in the blood. In such cases comatose symptoms precede and usher in the fatal event. There was some mental confusion and drowsiness towards the termination of the case, but no fatal coma presented itself; we cannot therefore attribute the death solely to this cause, but to this, combined with other injurious influences,—the inflammations in the chest, and the consequent dyspnoea; also the prostration consequent upon anorexia and continued diarrhoea.

In the *post-mortem* examination we have chiefly to notice the appearance of the lungs and the kidneys. The fluid contained in the pleura was not merely a serous effusion; flakes of yellowish opaque lymph, evidently the product of inflammation, were floating in it, and the same material was spread over the surfaces of the pleura. I would draw your attention to the yellowness and opacity of this lymph, differing from the paler more semi-transparent lymph, the result of acute inflammation, occurring in a healthy person, as showing that caco-plastic condition of the blood, which I consider the immediate cause of granular degeneration of the kidneys. There were also the marks of recent inflammation of the substance of the lung, being of that form which is called *lobular pneumonia*, in which the inflammation is limited to circumscribed patches. Dr. Williams (see "Cyclop. of Med." Art. "Pneumonia,") has pointed out that this form of pneumonia frequently occurs when there is much serous effusion on the surface of the lung; and the

consolidated or carnified state of the inflamed parts presenting the solidity of flesh, and without the granular appearance usually seen in pneumonia, is evidently likewise due to the pressure of the fluid in the chest, upon tissue infiltrated with adhesive lymph. The physical signs of pneumonia had been recognized only in the right lung, during life, but the marks of recent inflammation were likewise found diffused through the substance of the left, which was in the condition described by Laennec as engorgement or the first stage of pneumonia. Probably this state supervened very recently before death, caused, indeed, by the moribund state, being the *pneumonia agonizantium* of Laennec. There was some degree of tubercular disease in the lungs, which I notice is itself a mark of an imperfect state of the blood, similar to that which I consider the immediate cause of granular disease in the kidneys.

When we turn to the kidneys, we find them both larger than natural, but paler; not, therefore, at the time of death distended with blood, though, could we have examined them at the commencement of the disease, most probably we should have found them highly congested. As the kidneys were not enlarged by the blood they contained, we must suppose some morbid deposit; and this was evident enough upon examination, being the cause of the pale faded colour of the whole mass of these organs, and being likewise accumulated in patches of a still lighter tint. It was of a friable consistence, so that fragments were torn off attached to the capsule, which peels off quite clean from the healthy kidney. It is in this interstitial deposit that granular degeneration essentially consists; it is of the nature of lymph, the material of textural nutrition, or that which is poured out in excess from an inflamed part, only that here the lymph is not of a good quality; it cannot become fully organized, or if poured out in excess, it cannot be readily absorbed. When the blood is in that unhealthy condition to be capable of furnishing only this bad lymph, it may be deposited wherever inflammation occurs, or without inflammation, by deprivation of the ordinary nutritive process. Thus we may have granular degeneration commencing suddenly with symptoms of inflammation, or invading insidiously without any active symptoms. Dr. Copland, taking a similar view of the pathological nature of this disease—albuminuria, calls it “cachectic inflammation of the kidney,” an appropriate name for the acute form, but not applicable to all the more chronic cases, if I am right in considering that these may occur without any inflammation of the kidney.

This morbid deposit, whilst it is still recent, occasions an enlarged and flabby condition of the organ, chiefly affecting the cortical part, which is thus rendered broader than natural, but subsequently contracting, so as to render the kidney small and dense, and ultimately, in chronic cases, causing atrophy of the proper tissue, by the pressure to which it is subjected. I have seen the kidney of a person who died of the chronic disease reduced to the weight of one ounce, which is less than a quarter of its average weight. I have, in a former lecture,* pointed out the analogy between cirrhosis

of the liver and this disease of the kidneys. These diseases have much analogy likewise, as Dr. C. J. B. Williams has pointed out, with others of a serofulous or tubercular nature, in which we have a deposit of lymph in the substance of organs or tissues, more or less incapable of organization, invading the proper structure of the part, and frequently by its own tendency to contract and harden, shrivelling up and indurating the parts which it attacks. The grey induration of the lungs, which is considered as one form of tubercular disease, is an instance of this kind.

Other explanations have been given of the nature of this disease. Recently it has been represented as a fatty degeneration of the kidney, similar to that by which the liver is occasionally attacked. But I do not think this view satisfactory. The granular kidney has not the greasy feel or appearance which the fat liver presents; neither would a deposition of fat have a tendency afterwards to contract, and cause the atrophy of the organ in which it took place; the fat liver goes on increasing throughout its course. I think also there are many objections to the theory of this view of the pathology of the granular kidney, but we have not time to examine these in the present lecture.

OBSERVATIONS ON ASIATIC CHOLERA.

By T. L. WALFORD, M.R.C.S., Reading.

(Read at the Reading Pathological Society, Sept. 13, 1848.)

Mr. President,—In taking part in the consideration of this important question,—viz., the nature, seat, and treatment of the disease termed Asiatic cholera, it appears to me highly desirable to obtain definite views, if possible, of so dire a malady, so as to enable one to grapple with it under the most favourable circumstances; and as there are contained in Dr. Fletcher's posthumous work on “General Pathology,” views of this disease, such as we are seeking, and which to my judgment are no less correct than they are definite, I feel that I shall not be doing violence to the rules of this Society, by endeavouring to state them as I gather them from his work.

As to the origin of that which is the cause, the exciting cause of this disease, (call it a poison if you will,) there will be little hesitation, I apprehend, in believing it to be of a malarious origin; not in the sense of its being the result of chemical decomposition, occurring either in decaying vegetable matter or animal refuse, but rather a diseased vegetable secretion. In the language of Dr. Fletcher, (page 71,) “contagious and infectious miasms consist of combinations of principles, to the production of which organized beings, animal or vegetable, alone are adequate;” “and that it is not to this or that individual principle, but to the peculiar combination of them all, which can be effected in no other way than by secretion, that their pernicious effects are to be ascribed.”

The question whether the poison be absorbed into the blood, so as to constitute a “blood disease,” appears to me so untenable, that it seems preferable to omit

* See *Provincial Med. and Surg. Jour.* for 1848, p. 509.

the consideration of it, merely quoting the words of Dr. Fletcher,—“Whether absorbed or not, (and there is no question that they frequently are absorbed,) their action is still upon the irritable solids alone; and the only difference is, that when absorbed, the blood is made subservient to the diffusion of the exciting cause, of which it may be represented therefore as constituting a part; whereas, when not absorbed, the action of such exciting causes can be diffused only in the manner of sympathy; and we do not despair of being able to prove, or at least to render it highly probable, that the latter is by far the most common manner in which their action is extended.”—Page 48. See also pages 38 &c., 72 &c., and 99 and following.

Believing then, that the poison produces its effects upon certain solids of the body rather than upon others, we come to the question, where is the disease situated? Here I apprehend we can agree to a great extent in saying where it is not. We shall not hesitate to exclude the brain, the lungs and heart, the stomach and kidneys, from being primarily the seat of the effects of the poison, and that the manner in which these organs are affected is secondarily. If, by chemistry, we could prove that the discharge from the bowels had nothing of vitiated bile in it, we might with good reason locate the disease in the intestinal canal; but as that cannot be affirmed, the question to be considered is, whether it be a disease of the bowels or of the liver? and I think the balance of the evidence is most decidedly in favour of the latter. Under the head of etiology, at page 249, Dr. Fletcher, speaking of glandular secretions, says,—“The bile, instead of being opaque, viscid, and of a yellowish brown colour, is sometimes, as in cholera, semi-transparent, thin, and of a dirty straw colour,—changes which are attributed by Orfila chiefly to a vitiation of its resin.” “So much indeed has the bile been altered in this disease, that it has even been questioned whether it be bile at all, and not rather a vitiated secretion from the intestines.” “In modern times, also, it has been generally noticed, that an evacuation of pure bile is one of the best symptoms in cholera, and generally indicates recovery. But what does this shew, except that the disease is diminished; so that what was previously vitiated is now natural. We may as well question that the mucus in catarrh or gonorrhœa is mucus, or the urine in diabetes is urine, as that the bile in cholera is bile, since it is not a whit more changed than these; and there seems to be a regular gradation in the changes which it undergoes, in proportion to the severity of the disease, from the common autumnal cholera of this country, to the most violent degree of the Indian epidemics.”

At page 252, Dr. Fletcher observes, “That the proper secretion of any gland takes place at the *radicles* alone of the ducts of which such a gland is essentially composed, consequently that it is only when such radicles are the seat of inflammation that such proper secretion is increased. Hence it is easy to explain the apparent anomaly, that in a proper hepatitis we have not cholera;—in a proper inflammation of the pancreas no pyrosis;—in a proper nephritis no diabetes;—and in cynanche parotidea no pyalism: so far from it, there is a suppression, to a greater or less degree, of the proper secretion of the gland. But this supports the doctrine, that secretion is always increased by inflammation, for the seat is now the mucous membrane

of the ducts, and the increased secretion and swelling in them produces obstruction to the proper secretion of the gland, and thus gives rise to its suppression.” It will thus be seen, that cholera, in the opinion of Dr. Fletcher, is an inflammation of the secreting portion of the liver, and in proof of the correctness of that opinion, I would observe, that in proportion as we succeed in restoring a healthy secretion of bile, are we successful in treating the disease? Again, what means have been followed by the largest amount of success, small though that may be? Calomel. What medicine has been used so cautiously by all, and altogether rejected by some? Opium. Now, surely this would not be the case if the mucous membrane of the intestine were the seat of the disease. Again, is there any affinity between English and Asiatic cholera? I believe they differ only in degree. Lastly, what treatment most quickly cures our autumnal cholera? Calomel and rhubarb: at least according to my experience.

Having thus called the attention of the Society to the opinion of, (according to the late Dr. James Johnson,) one of the most original thinkers of modern times, it may be as well to run through the various symptoms of the disease, to see whether the opinion I have read will satisfactorily explain them. Of the nature of the stools, I have quoted what Dr. Fletcher had to say in defence of their hepatic origin. But this does not forbid the presence of some secretions from the mucous membrane of the alimentary canal, excited, as it would naturally be, by the passage along its tract of so much vitiated secretion. The vomiting which attends night sometimes take place as the result of the powerful contraction of the abdominal muscles, but more frequently as the result of the inordinate stimulus to which the stomach is subjected from the vitiated secretion within it. Next let us take the violent cramps, and what are these but the consequences of the impression made upon the spinal marrow, by the presence in the bowels of vitiated secretion, and by the inordinate peristaltic action going on there, thus giving rise to reflex action, similar in every respect to the same symptom occurring during the night in gouty subjects. When gouty, or during pregnancy, from irritation of the gastro-intestinal mucous membrane, as a consequence of that condition, the distressing tormina and the hurried dejections are appropriate concomitants of such a condition of the alimentary canal.

The torpidity of the kidneys, indicated by the non-voidance of the urine, is clearly dependant on the depressed state of the circulation, coupled with suspended digestion, and diminished cerebral influence. The coldness and blueness of the surface is equally plainly dependant on torpidity in the function of the lungs, whilst that torpidity itself stands as an effect of the diminished power of the heart to propel the blood throughout the system in its wonted manner. As to the heart itself, its enfeebled power must be considered as the result of the shock to the heart itself, which the presence of the disease has occasioned, whereby its irritability has been exhausted. Of the state of the blood, it is observed by Dr. Fletcher, p. 95,—“In Asiatic cholera the blood has by some, (Dr. Stevens, &c.) been represented as primarily affected, turned into an infected jelly for one thing, and of a prodigiously dark colour for another, the latter change dependant,

of course, on too little salt in the serum. These, however, are not primary, but secondary, changes of the blood, and arise from the depression of the powers of circulation, so that through the tardy flow of the blood through the parenchyma, its molecular changes are so sparingly affected, that it undergoes a partial coagulation. The use of warm saline injections is not to dilute the jelly aforesaid, nor to impart salts, but merely to afford a transitory stimulus to the heart, and accelerate for a time the circulation."

Having glanced at the chief symptoms in this disease, it remains to notice the order in which they manifest themselves, observing that the interval between them may vary in every case. In this, as in every disease, there is a stage (the latent) which can only be recognized by its effects; so that at one and the same time, we behold the direct effects of the disease, and its indirect or sympathetic effects. Thus, within a short time of the commencement of vomiting and purging, we have also, in some cases, the depressed power of the heart; but whether this exhaustion of the power of the heart is solely caused by the disease through sympathy, or whether the disease affect the heart through the brain, perhaps, it is not possible clearly to determine; but this much may be affirmed, that only in proportion as we remove the disease, shall we remove the effects, and so likewise with regard to the state of the lungs and kidneys.

That the disease is inflammation of the secreting portion of the liver will be borne in mind, and that state existing, the process of secretion at once commences, and its products correspond with the peculiarity and intensity of the exciting cause.

For Dr. Fletcher's views of the nature of inflammation, and of the system of nerves, by means of which its sympathetic effects are produced, I must refer the reader to his work. A bare enunciation of his doctrine might not command assent, and it might deter the mind from further investigation. Those only who understand his physiology, can appreciate his pathology.

On the subject of those who are most liable to be affected, it is well known that the vast majority of cases occur in this country amongst those who belong to the poorer classes—the ill-fed, the badly clothed, and badly housed, the beverage of whom is too often unwholesome, and whose bodies have been frequently found to be the seat of various organic maladies.

The treatment of this dire malady next falls to be noticed. The gravity of the disease must be borne in mind,—the shortness of the time we have for the use of remedies,—the impossibility of the patient living many hours unrelieved. All these considerations point to the necessity for decision, promptness, and vigour. And what have we to do? If what I have stated be true, the relaxed, debilitated, exhausted, distended, overloaded capillaries of the liver have to be relieved. Here we shall be agreed I imagine. If the patient be seen in the first hour or two of the attack, a vein should be opened and a certain quantity of blood drawn, if possible, according to the bulk and stamina of the individual. This done, I should be inclined to try the effect of a bandage of flannel about a foot wide, passed some five or six times round the body over the region of the liver, that the patient should be placed in an open bath, and water as hot as could be borne should be poured over the flannel for half an hour;

he should then be removed, having an oiled cloth put over the flannel to keep in the heat and moisture. This application of caloric follows as a stimulant to these vessels, it having been attempted to relieve them partially of their load by blood-letting. Whilst the bath and water are preparing, I should give a dose of calomel and colocynth in as soft a form as can be swallowed—say five grains of each—hoping thereby to hurry from the alimentary canal any irritating matters there. An emetic where vomiting exists, I can see no necessity for. The pills should be followed by an effervescing dose of citric acid and bicarbonate of potass, to be repeated every hour. A mouthful of potass water, [?] or thin clear gruel with or without brandy, may be taken if anything be desired, to quench the thirst. When the patient has been removed from the bath, and a couple of hours have elapsed since the detraction of the blood; if the heart's action be not recovered, the warm saline injection into the veins should be had recourse to,—not, as Dr. Fletcher observes, "to dilute the jelly aforesaid, nor to impart salts," but merely to afford a transitory stimulus to the heart, and thus accelerate for a time the circulation. Throughout the treatment, all that pains the bowels and stomach should undergo the observation of the medical attendant. The calomel should be repeated in doses of two grains, in the form of a pill, made with extract of liquorice, every hour, and the effervescing dose should be repeated equally often. By this latter medicine the intestines would be excited to pass on their contents, and thereby lessen the amount of morbid impression upon the spinal marrow, the cause of the excruciating cramps. Should the bowels cease acting, it would be as well to add a little sulphate of magnesia to each, or to alternate doses of the effervescing draught. As soon as the evacuations give evidence of the presence of healthy bile, the interval between the doses of calomel should be lengthened as much as possible. In the event of the heart's action failing, recourse should be had again to the warm saline injections; and if the stomach will retain it, to some brandy in warm thin gruel. At this stage of the disease, remedies having failed to rescue the patient, the use of galvanism through the liver appears to me worthy of trial.

There is one other means which should be used from the commencement, and that is, friction with some warm stimulating liniment, say equal parts of turpentine liniment, simple camphor liniment, and soap liniment. This should be used universally when the patient is not enveloped in the hot flannel bandage around his belly, and when he can have that means, it should be omitted in that part of the body until experience has proved its uselessness. A more potent remedy may be found in the use of boiling water applied to some cloths placed over the region of the liver for the purposes of vesication. It appears to me that if some four or six hours at the furthest, have been unsuccessfully employed in combating with the disease, that no further time should be allowed to elapse without the trial of this remedy. These means failing to bring about the third stage of the disease, I must leave to empiricism to suggest what next should be done. But supposing the third stage arrived at,—viz., the secretions lessened and improved, the heart's action restored, the vomiting abated, then, perhaps, the judicious use of

morphia may be tried with good effect. But in this stage we must be on our guard against secondary inflammation; for the diminished irritation in which every organ has been, is a state liable to excessive irritation, on the recovery of the part originally affected, and which, if you produce it, will assuredly end in that degree of diminished irritation constituting inflammation. Therefore, now, the less we can do, the better. Stimulants should be withdrawn,—repose should be encouraged,—nourishment of the highest kind should be administered, and thus nature would have a fair chance of avoiding the breakers which were a-head of her, when escaping the rock on which she had been so nearly wrecked.

There are one or two other points of a secondary nature which it may be as well to notice. The position of the patient is one such: of course the horizontal position must be enjoined; but that is not all, let him lie anyhow, rather than on his back—either side, or prone, if he please. He should also be assisted in getting out of bed, in turning, and not allowed to sit upright. The heart is too weak to allow of its being benefitted by the return of the blood being hindered by the sitting posture, and the brain likewise cannot spare any of the power which the blood in its vessels receives from the enfeebled heart. The temperature of the apartment must be kept steadily high.

The treatment which I have thus sketched will be looked at as embodying a general rule. Cases will occur where it would be losing time (to say the least of it,) in attempting to bleed. Every medical man has patients which he knows cannot bear the loss of blood, and such he would not hesitate to consider unfit subjects for that remedy; and so likewise will every other suggestion be subjected to the judgment of the medical attendant, and adapted to the individual's case before him. It must also be remarked, that with such a disease as Asiatic cholera attacking certain individuals, the result must necessarily be fatal; and well will it be for the practitioner when his knowledge of his patient's constitution enables him to judge correctly of what can be borne by him. It seems hardly necessary to say anything of the treatment of any secondary affection which may arise to interrupt and prolong the recovery of the patient.

OBSERVATIONS ON SCURVY

AS IT WAS DEVELOPED

IN BATH AND ITS NEIGHBOURHOOD, IN
THE SPRING OF 1847.*

By JOHN BARRETT, Esq., F.R.C.S.

(Read at the Quarterly Meeting of the Bath and Bristol Branch of the Provincial Medical and Surgical Association, December 21, 1848.)

Of few diseases can it be more truly said that prevention is better than cure, than of scurvy. Under favourable circumstances its cure is tedious, and the means of cure are not always to be met with in the circumstances under which it occurs. But it is not

only that its cure is tedious, and sometimes for a time impossible, it is attended with consequences of a very dangerous character,—e.g., the effect it produces on old surgical cases; the re-opening of wounds; the disunion of fractures; and it certainly lays the foundation of fatal chest and other diseases, by breaking down the constitution. If we judge of it by the number of deaths in its recognized appearance, we may probably consider it a matter of secondary importance, but this, I have before said, is a very inadequate manner of judging. It is not a disease of sudden occurrence, it requires months' duration of the preparatory circumstances. But as there can be no doubt that it has appeared, and frequently, (where even the profession may not have suspected, it is constantly occurring,) is there, I would ask, no reason for fearing that a disease which has decimated armies, and destroyed fleets, may in our day regain a fearful and destructive influence, if we do not remove the causes of its occurrence, or if by foolish directions we increase them. There is much wisdom in that part of the address from the College of Physicians on cholera,—"The Committee do not recommend that the public should abstain from the moderate use of well cooked green vegetables, and of ripe or preserved fruits. A certain proportion of these articles of diet is, with most persons, necessary for the maintenance of health, and there is reason to fear that if they be generally abstained from, now that the potato crop has in a great measure failed, many persons, especially among the poor in large towns, will fall into that ill condition, which, in its highest degree, is known as scurvy, and that they will in consequence be the readier victims of cholera."

There is one point to which, I am ashamed to say, I have not directed either my own, or my correspondent's, attention. The Registrar-General, in his return for the quarter ending December 31st, 1846, says,—“No mention is made of the potato disease having had any direct connection with the mortality. The potato in a state of partial disease, has no doubt, been extensively consumed, without giving rise to any specific malady in man, or indeed having any appreciable connection with the disorders of the bowels, and fever, which were prevalent about the time the last crop came into use.” I asked one gentleman, who said some of his scurvy cases had not been debarred potatoes, whether they had been good or diseased, but this he could not inform me. A poor woman, aged 76, applied to me, October 31st, this year, for griping pains in the bowels, increased on pressure; evacuations once a day, relaxed; white dry tongue, and weak pulse. Three weeks before she ate some potatoes, which were very watery and yellow, and had not been well since. She took small doses of calomel and opium for a few days, which cured her.

It is a question of much interest—what is the nature

* Continued from page 177.

of those changes in the animal economy which give rise to the symptoms of scurvy. Its most efficient external cause, the absence of certain organic acids from the food is so definite and determined, that if there be any cases in which the discoveries of the chemist can be brought to bear on the investigations of the pathologist we should expect this would be one of them. Yet, hitherto, there seems to have been hardly an attempt at a pathological *rationale* of scurvy. The idea that the globules of the blood are in it, dissolved in the serum, is abundantly disproved by the fact that, scurvy blood will separate as rapidly into clot and serum as healthy blood; but I am not aware of any attempt to explain how it is that the absence of an organic acid from the food is attended with an improper excess of the water, fibrin, albumen, and the salts, with a deficiency of the hæmosine of the blood, for this seems to constitute the morbid alterations of the blood in scurvy. Dr. Budd remarks, "The study of scurvy is most instructive to the pathologist, showing as it does, the variety and importance of the effects which may result from a primary alteration in the quality of the blood, independently of any morbid change in the solids." I have no wish to underrate the importance of these morbid alterations in the blood, but I question whether future investigations on this subject may not show that this conclusion is rather too exclusive.

There is another fluid in the body possessing properties strongly distinguishing it from the blood, for a knowledge of which we are indebted to Liebig, and though attention has only lately been directed to it, there is reason for believing that it plays a very important part in the animal economy. "Besides the blood and fluids contained in the lymphatic and absorbent vessels, there exists in flesh a considerable quantity of a peculiar fluid, enclosed either in peculiar minute vessels, or more probably in the cells of the fibrous and cellular tissues. To this liquid Liebig gives the name of the juice of flesh, and he has lately subjected it to a minute investigation with very important results."—"Turner's Chemistry, 1848, p. 1280.) The important difference between this fluid and the blood is, that whereas, the blood is alkaline, containing phosphate of soda—an alkaline salt; the juice of flesh is acid, containing phosphate of potash, and acid salt, and several organic acids, the most important of which is the lactic. Now, it is interesting to remember that though some animals will live on food wanting in the vegetable organic acids, man will not. The carnivorous animals will of course live on flesh only which contains lactic acid, but there is abundant proof that man will not long subsist on flesh or even milk without scurvy, but must have a supply of food containing vegetable organic acids. We know that these organic acids, composed as they are, of the same ultimate principles,—i. e., carbon,

hydrogen, and oxygen in different proportions, are convertible into one another;—thus, citric acid, "when melted with an excess of caustic potash, is resolved into oxalic and acetic acids and water, which is merely a different arrangement of the same elements."—"Turner's Chemistry, p. 1039.") It is surely, therefore, no very bold hypothesis that in such animals as the carnivorous, the lactic acid may be derived from their food as lactic acid, but that the organization in man may require that it be derived from other organic acids which undergo chemical change after they have entered the body; and that unless such a change go on health cannot be kept up, but certain morbid consequences follow. And if the gastric juice be "very nearly identical with the juice of flesh, or fluid of the muscles," ("Turner's Chemistry," p. 1293,) we can easily understand how a deficiency of the means of supplying the animal system with lactic acid might lead to a disease presenting features of depraved nutrition like scurvy. Again, Liebig has shown that only a small fraction of the whole amount of bile can be detected in any shape in the fæces, and that the bile is unquestionably reabsorbed in the intestinal canal and re-enters the circulation, where it soon disappears; and if it be correct, as is supposed, "that the bile is resolved into lactic acid and other products before it is finally consumed," ("Turner's Chemistry," p. 1314.") any derangement of the digestive function, any affection of the liver, such as scurvy has been considered to present, would speedily react on the system and diminish the quantity of lactic acid, and consequently the chemical actions involved in its presence, and hence might follow the necessity of relieving this viscus which has been so strongly insisted on. Again, in his "Animal Chemistry," Liebig endeavoured to show, taking the then admitted formulæ for bile and for blood, "that the latter fluid, with the addition of a little water and oxygen, might be resolved into cholic acid and urate of ammonia,—that is, into bile and urine." Now, I would remark, that lactic acid is acetic acid, with two proportionals of water and one of oxygen. If, then, we were to suppose that in the liver this quantity of oxygen and water is removed from the lactic acid then existing in the juice of flesh and acting on the blood, we should get as products, bile, acetic acid and urine; the bile discharged in the alimentary canal, the acetic acid carried to the gastric juice, the urate of ammonia, by further oxidization, yielding finally carbonic acid, ammonia, and urea. But if there should be a deficiency in the quantity of lactic acid, of course this chemical change will be interfered with, the blood would not be exhausted in the liver, and might not this lead to the congestion of that organ?

In scurvy blood, whilst fibrin and albumen are in excess, hæmosine is deficient in quantity. But albumen and fibrin may be considered elementary

parts of the body, whilst hæmotosine, though possessing many properties in common with albumen, is probably the result of chemical change of one or both, and if this be so, its deficiency and their excess would seem to imply a deficiency of chemical action.

Another morbid condition in the blood of scurvy is the excess of the salts. Now, the most important salt of the blood is the phosphate of soda, which gives it its alkaline character, whilst the juice of flesh contains the phosphate of potash, an acid salt which is "the only phosphate that can be formed by an animal from food containing salts of potash without soda, such as inland plants." There can be no doubt that the function of the acid salt, the phosphate of potash in the juice of flesh, and apparently also in the gastric juice, is as important as that of phosphate of soda in the blood," and if the want of vegetable food should deprive the animal of the proper means of forming this, the balance of acidity and alkalinity of juice of flesh, and blood, would be interfered with, and all chemical changes involved in such proper balance and proportion might be also. The gastric juice contains free phosphoric acid, but if the food be principally salt meat, and wanting in fresh vegetables, it will necessary expose soda, not potash, to the acid, and may thus lead to that combination which gives the alkaline character to the blood, and may lead to the excess of the salts found in scurvy blood, whilst it may deprive the juice of flesh of its necessary acidity, and break up the proper balance as before observed. It is a remark worth consideration, the salting of meat is detrimental to its nutritive qualities, because an exchange takes place between the salt and the juice," that is, not only is too much salt carried into the stomach, but it is also deprived of the acids contained in the juice of flesh.

We have then, I think, reason for believing that in scurvy there must be very considerable suspension of those chemical changes which go on in health, but chemical action never takes place without a development of electricity. Our attention was called to this subject by Dr. Davies, at our summer district meeting, in a paper on "Traumatic Paralysis," treated by electro-magnetism. He then referred to the interesting facts relative to the development of electricity in the animal economy, brought forward by Liebig and Matteucci, and of which the following mention is found in "Turner's Chemistry," p. 1320:—"Another probable function of the substances which give acidity to the juice of flesh and alkalinity to the blood, is the production of electrical currents. It has been shown by Matteucci, that such currents exist in the body, and we can easily see how they may arise when we observe two fluids, one acid, and the other alkaline, separated by a membrane permeable to one or both, and the fluids in contact with muscle, and with nervous matter. At the request of Liebig, Buff constructed piles of

discs of pasteboard, steeped in blood, with slices of muscle and brain, which showed a powerful current from the blood to the muscle." But supposing the alkaline qualities of the blood to be increased (as by analysis we know they are in scurvy,) and the acid qualities of the juice of flesh to be decreased, should we not expect that there would be a constant decrease of electrical development. Now, from Dr. Davies's paper, for to this I must refer, not having read Matteucci's lectures, it would appear, that in rheumatism there is a marked deficiency in electricity; that in all muscles there is a constant current of free electricity, bearing a direct ratio to the vigour of the animal, and the degree of development of the muscular structure. But what symptoms are more constant or more strongly marked in scurvy than the absence of muscular vigour, and the presence of muscular pain, debility, and rheumatism. And may we not conclude, that in the suspension of certain chemical actions in the animal economy, the derangement of certain states of chemical proportion, in the different fluids, and in the consequent interruption of electrical development, to be found at once a *rationale* of the morbid changes which take place in the structures of the body, and of the symptoms of the disease. Dr. Davies also states that the higher the animal is in the scale of being, the greater is the amount of electricity developed. I have called your attention to an important difference between the carnivorous animals and man, who stands highest in the scale of organization; they will continue in a state of health living on flesh containing an organic acid—the lactic acid; but man requires a vegetable organic acid, and one which, if it should be a source of lactic acid contained in his muscular fluid, must be so by undergoing chemical change, and thereby giving rise to electrical development. And may we not, therefore, conclude that the necessity for this superior degree of electrical development, connected, as it is, with his superior organization, is one reason why he requires in his food a vegetable organic acid?

These remarks have extended to such a length that I fear I shall be looked on as hopelessly affected with the *cacoethes scribendi*. In palliation, I must remind you, that I have been bringing before you the opinions of a number of medical men, on a question of really national interest. Some credit, however, I must take to myself for sparing you the infliction of all my scribblings. I may say with Pope,—“For what I have published, I can only hope to be pardoned; but for what I have burned, I deserve to be praised. On this account the world is under some obligation to me.”

CONGENITAL ABSENCE OF THE CRYSTAL-LINE LENS.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

The following description of congenital affection of the eyes, although not occurring in the human subject, appears worthy of record in the pages of the *Provincial Journal*.

I remain, Sir, your obedient Servant,

AUGUSTIN RICHARD.

Red Lodge, Bristol,

March 22, 1849.

The subject was a calf, born blind, and unable to follow its mother about: according to the account of the butcher, being totally blind; and the examination of the eyes after the animal was killed shows that, if it had any power of vision whatever, it must have been merely the power of distinguishing light from darkness.

Both eyes were smaller than calves eyes usually are, and both presented, externally, opacity of the cornea, to which the iris was evidently adherent. In one there were three small surfaces of adhesion, in the other only one; the rest of the cornea was transparent. In one eye the pupil was visible, but in the other (in which there were the three opacities,) it could not be distinguished through the cornea. The iris was much thinned at the adherent points, so much so as to render it doubtful whether it existed there at all, or whether it was not the separation of the ciliary border of the iris from its attachments, allowing the ciliary processes to bulge forwards into the anterior chamber, as far as the cornea. The margin of the pupil was almost entirely adherent to the subjacent parts; in one eye the aperture had its natural size, in the other it was very much contracted. The choroid and retina were healthy, but upon dividing them, so as to turn out the contents of the globe, it became evident that there was no lens. The posterior surface of the iris was in contact with, and adherent to, the anterior surface of the hyaloid membrane. The ciliary processes were present; and in one eye the capsule of the lens was tolerably distinct, in the other it was not to be found. The lines upon the anterior surface of the vitreous body, called "the ciliary zone of Zinn," were in the usual form. The vitreous humour itself was perfectly transparent. The condition of the eyes was therefore the following:—Absence of the lens, synechia anterior and posterior, (adhesion of the iris in front and behind,) and staphyloma of the cornea and iris.

It appears to me most probable, that there was at one period of intra-uterine life, an escape and loss of the crystalline lens, and that the other changes were the result of the subsequent inflammatory process, at any rate the state of the organs, as far as their external appearance went, very much resembled the eyes of those who have met with an accident, and lost the lens through an aperture at the edge of the cornea, leaving the healing process to nature.

Cases of congenital diseases occur sufficiently frequently, both in the eyes and other organs, to render it quite certain that the fœtus is subject to most, if not all, the complaints by which the body may be affected after birth.

PROVINCIAL

Medical & Surgical Journal.

WEDNESDAY, APRIL 18, 1849.

We avail ourselves of the present opportunity to direct the attention of our readers in a more special manner to the notice inserted in the last number of this Journal, respecting the therapeutical value of cod-liver oil in phthisis pulmonalis. It will, we are assured, be readily conceded, that there is no subject upon which the combined experience of the Provincial Medical and Surgical Association can be brought to bear, of deeper interest to humanity, than one in any manner connected with that devastating malady, and we trust that Dr. Ranking's appeal to the individual experience of such of our associates as are familiar with the effects of cod-liver oil in its treatment, will meet with a ready response.

We are the more earnest in our wishes on this matter, because we are confident that the enlightened body of practitioners, of which this Association is composed, is capable of affording a mass of valuable information on any point, such as no other section of the profession could produce, and we should therefore regard the results of their communications with much interest. We need not remind them that in according their aid towards the elucidation of the question proposed, they will be carrying out one of the main objects of the Association.

As far as we understand Dr. Ranking's request, it will not involve any great degree of trouble on the part of those who may favour him with communications. He is anxious to have information on the following points:—

1. The number of cases in which the oil has been exhibited, with the proportion of successful and unsuccessful cases.

2. The stage at which the oil has been exhibited, whether in the incipient or advanced.

For convenience sake it may be advisable to divide the cases of phthisis into three stages—the *incipient*, in which the tubercular matter is not softened, as indicated by the following signs:—Slight depression and immobility of the subclavicular regions, with rough, jerking, or deficient respiration, and some dulness on percussion; the second, in which the tubercular matter is softening, the signs being as before, with the exception that the respiratory

murmur is replaced by mucous râles; and the advanced stage, with cavity or cavities.

He also wishes to be made aware of the amount and duration of the improvement in the several cases, in regard to the expectoration, diminution of cough and night sweats, increase of weight, &c., as well as of any unfavourable symptom which has supervened upon its employment. These questions, we are sure, will be answered by such of our associates as have had experience of the effects of the oil, both with willingness and facility.

We shall look forward with interest for the result of Dr. Ranking's investigations. Many, we are aware, regard with apathy any form of medication connected with consumption, but we are well assured, from our own observations, as well as from the concurrent testimony of Dr. Williams (*London Journal of Medicine*, No. 1,) and others, that in cod-liver oil we possess a means, if not of curing consumption, yet of suspending its ravages for months, and even years, superior to any other which has ever been brought before the notice of the profession.

If Dr. Ranking's enquiries succeed in establishing this our present belief, upon the only sure basis afforded by extended investigation, he will have accomplished a task both creditable to the Association, and of the highest value to society.

Proceedings of Societies.

BIRMINGHAM PATHOLOGICAL SOCIETY.

December 7th, 1848.

FRANCIS ELKINGTON, Esq., in the Chair.

SPONTANEOUS AMPUTATION IN UTERO.

Mr. F. Elkington presented a specimen of spontaneous amputation of one lower extremity of a fetus in utero, and gave the following description of the body of a male child, born the 10th of September, 1848:—It presented no symptoms of life; the integument of the scalp is of unusual thickness, containing fat; no ossific matter has been deposited higher than just above the base of the brain, the brain being covered in by a cartilaginous membrane, easily cut with the scalpel, the course of the sutures being indicated by white lines; the membranes and substance of brain appeared healthy, as far as an imperfect examination can determine; behind the situation of the posterior fontanelle is a pendulous body, more than an inch long, composed of integument and dura mater, which latter structure comes through a bevelled opening in the cartilage; the conformation of the chest and abdomen are normal; thymus gland weighs rather

more than four drachms; heart healthy; lungs small and solid, lying near the spine; liver, stomach, and intestines, appear healthy; a single *cyst*, about the size of a *hen's egg*, containing a glairy fluid, in the lesser omentum; kidneys large, pale in colour, containing numerous small cysts, the difference between the tubular and cortical substance being in some parts nearly, and in others entirely, lost; the left lower extremity presents a well-marked specimen of spontaneous amputation in utero; that this has taken place will be readily perceived on examination of the part, a thin cord being present, shewing where the other portion had probably been recently attached. The other extremities well developed.

IMPERFORATE ANUS.

Mr. Elkington also communicated a case of imperforate anus in an infant in which the rectum burst fifty hours after birth. The following is a description of the lower part of the intestinal canal of a mature child which lived fifty hours, presenting no peculiar symptoms until a short time before its death:—It may be noticed from the preparation that the *rectum* terminates abruptly about an inch from and below the level of the *anal* aperture, the gut being firmly united to the surrounding structures by a *fascia-like membrane*. Some distance up the bowel a ruptured opening has taken place, about the size of a shilling, the part around being thinned for some distance; a large quantity of fecal matter escaped into the cavity of the abdomen, thus producing the death of the child.

CORRODING ULCER OF THE UTERUS.

Mr. Simons narrated the following cases of this affection:—

Elizabeth Bromage, aged 72, the mother of eleven children, has been suffering from disease of the uterus for twenty years. She came under my care about twelve months since; she was then suffering from constant vomiting, great pain in the uterine region, with enlarged inguinal glands. There was a constant discharge from the vagina, of a muco-purulent nature, mixed with blood, and having a smell somewhat like garlic. On examination, the entire os uteri and one half of the posterior wall of the organ was destroyed by ulceration; and there was also a ragged ulcerated opening through the anterior wall of the vagina into the bladder, about an inch behind the commencement of the meatus urinarius. The fundus of the uterus was healthy. The inguinal glands had suppurated.

Ann Bott, aged 32, married eleven years, the mother of four children, the youngest being six years of age; has been separated from her husband (a soldier,) for six years; her general health was good until the last nine months; had always menstruated regularly until nine months since, when, after suffering much pain in her back, she had an attack of menorrhagia, which lasted about nine weeks; from this time till her death she had constant pain in the uterine region, with a discharge of mucus (occasionally mixed with blood) from the vagina. She came under my care about two months since, when she complained of constant vomiting, and of very severe pain in the uterine region. There was no enlargement of the glands. Upon examination per vaginam the posterior

lip of the os was found to be ulcerated. She died, worn out by pain and by the vomiting.

Sectio cadaveris.—The os uteri was entirely destroyed by ulceration; the cervix was also in part destroyed by the ulcerating process, which had also extended over the portion of vagina connected with the uterus, but had not produced any perforation of its walls; the body of the uterus healthy, its lining membranes of a deep colour.

APOPLECTIC CYST IN THE BRAIN.

The following case was communicated by Dr. Russell:—

Mrs. A., aged 77, of full habit and good health. She had been a nurse. About four years ago she had an attack of hemiplegia, the right side being affected. She was bled from the arm, and she gradually recovered; the right arm has ever since been weak, and her speech has remained a little drawing, but she could walk as well as ever. I was sent for November 10th, and found that she was again suffering under an attack of hemiplegia, the left side being affected on this occasion. She was speechless, but apparently sensible; the left pupil was rather more dilated than the right, which was natural; she vomited whilst I was present; she passed a considerable quantity of water since her seizure involuntarily; pulse was regular, and natural as to power; some blowing out of the cheeks, and some stertor; great drowsiness. For some days previously she had been very cross. She was seized at half-past twelve, as she was preparing to dine, having taken a walk after her breakfast. She retained the power of speech some time after the use of the left side was lost. I applied leeches to the temples, and ordered a turpentine enema. Her state quite precluded any active treatment. She lived a few hours more than two days and a half from the time of the attack. She remained sensible about sixteen hours, but afterwards was motionless, and apparently unconscious. She never swallowed; her bowels never acted; she passed urine involuntarily; she had no convulsions; her pupils were quite insensible.

Sectio cadaveris sixty hours after death.—Decomposition had commenced; trunk fat under the skin, and in the anterior mediastinum. Lungs rather loaded with bloody fluid. Heart contained a good deal of dark, half-coagulated blood, on both sides: its lining membrane and its valves very deeply stained with blood; the right auricle completely dyed all through its coats with the same dark tinge, presenting externally a remarkable appearance. When the heart was opened air issued, and there was some crepitation on pressing its walls; no atheroma in the commencement of the aorta, nor was the lining membrane of that vessel at all stained. The brain was quite firm, and did not indicate decomposition having commenced; the membranes rather full of blood; the grey and white matter very distinct; there was a large apoplectic clot in the right hemisphere, it lay on a level with the ventricle, but quite clear of it, and extended along the middle third of the hemisphere; internally it appeared so near the ventricle as to discolour its walls, but did not rupture them; externally it was covered by fully an inch of cerebral matter, excepting in one part, where it had formed an irregular passage to the surface, and was just covered in by the membranes, and by a thin layer of brain; it passed downwards, becoming gradually smaller. In the left hemisphere was, (what was probably the remains

of the former effusion,) a narrow rounded passage, which would about admit a quill, and about half an inch in depth; it was first opened on a level with the roof of the ventricle, and passed nearly perpendicularly downwards; it was situated about three quarters of an inch outside the ventricle, and nearly in the middle of the long diameter of the hemisphere; it contained a spongy cellular tissue, and its lower part a small, firm, smooth substance, quite unattached.

DISLOCATION OF THE CERVICAL VERTEBRÆ.

A case of disarticulation of the fourth cervical vertebræ from the fifth, was detailed by Mr. R. L. Baker.

I was summoned to the patient from whom this specimen was taken on Friday evening, the 10th of November, at ten o'clock. He was a strong muscular man, aged 25, about the average height, of drunken habits, but had never suffered from disease of a serious nature. His employment, that of a gentleman's servant. In this capacity, whilst going from Birmingham in his master's cart, he either was thrown or fell from the cart, and received the following injuries:—Various abrasions and contusions of a slight nature on many parts of the body; an oblique contusion occupying the middle third of the space between the left parietal protuberance, and the external angular process of the frontal bone; a lacerated wound of the pinna of the left ear; there was also a bruise on the right side of the head, corresponding to the one on the left in situation and appearance, rendering it probable that the wheel had passed over his head; and another bruise at the back of the head, upon the superior part of the occipital bone, and upon the lambdoidal suture; there was no appearance of a bruise upon the integument at the back of the neck. His limbs were completely paralysed, both upper and lower, but warm, although for an hour he had been lying on the damp ground before he was found. The iris was insensible to light, but not dilated; the respiration was slow, easy, and not at all stertorous; his pulse was slow and intermittent. He muttered incoherently, but could not be roused to answer any questions, but the person who first found him on the road says that he requested to have his nose rubbed by a bystander, indicating sensibility of the face, but paralysis of the arms. He swallowed with great difficulty liquids that were given him. On elevating his head there was not the slightest opposing muscular effort, and on raising him in bed the head dropped forward, and the neck seemed unusually loose and unresisting, and the spinous process of the seventh cervical vertebra appeared more prominent than natural, although I thought not sufficiently so to afford any decided guide for the diagnosis. Understanding from his friends that he was drunk, which was afterwards proved at the Coroner's inquest, and in the absence of stertorous breathing, or convulsive contraction of the muscles, I considered that there was no compression of the brain, and thought that the adoption of any treatment would be unsatisfactory. I decided to wait until the next morning, in hopes that the effects of the stimulants would be gone off, and that I should then be able to form a satisfactory diagnosis, for, of course, from the paralysis of the limbs, and the condition of the pulse, I concluded some serious injury had been inflicted upon the spinal cord. On leaving him I requested his

friends to let me know if any change took place in the night, and if not, I promised to see him in the morning. I did not hear from his friends, and therefore I visited him the next morning, at ten o'clock. I found his pulse much weaker than the night before, and still intermitting; the surface of his body pale, and much lower in temperature. He was evidently fast sinking, and expired an hour after I had left him.

At the *post-mortem* examination I observed the external marks before enumerated. On opening the head I found the membranes of the brain had their usual appearance, with the exception of the pia mater, the vessels of which were rather congested. The cerebrum and cerebellum were firm and quite healthy in appearance, but on cutting through the spinal cord, and placing the head in a depending position, a quantity of fluid blood, of a dark colour, issued from the foramen magnum. In cutting through the integuments at the back of the neck, I found great extravasation of blood between, around, and within the structure of the muscles near the seat of injury, which later consisted of a disarticulation forwards of the cervical vertebra, at the fourth and fifth bones. The intervertebral substance was torn, but there was no fracture of the body of either bone. A fracture extended through the right superior articulating process, and across the base of the transverse process of the fifth vertebra. The cord was crushed; fluid blood was effused into its sheath; brain healthy.

OVARIAN DISEASE.

A preparation, consisting of cysts in the ovary and in the walls of the vagina, was exhibited by Mr. F. Elkington.

The preparation shews a well-marked specimen of ovarian disease in its earliest stage. The cyst is about the size of a pullet's egg, apparently unilocular, its contents transparent. There is a second cyst the size of a grape suspended by a long pedicle from the lower surface of the diseased ovary. The preparation also shews a cyst the size of a pigeon's egg, situated at the upper part and left side of the vagina. It contains a fluid and is nearly transparent. It appears to be covered on its inner surface only by the mucous membrane of the vagina, and on its outer surface by condensed cellular membrane. The fibrous coat of the vagina is not continued over the cyst. Its fibres are seen terminating in a circular or crescentic margin, or well-defined edge, forming a round opening occupied by the cyst. The uterus healthy. The preparation was removed from a lady who died suddenly of apoplexy. She was 48 years of age, and the mother of six children. Three years before her death I attended her for ulceration of the os uteri. On introducing the speculum I noticed a small transparent body the size of a large grape, situated about the commencement of the upper third of the vagina. It appeared to hang over the edge of the speculum and rather to obstruct its passage, but on pressing the instrument onwards the tumour disappeared. In making a digital examination, I could not feel any tumour, but the wall of the vagina at one part felt softer and less resistant than usual. I had to use the speculum many times. On several occasions I made a digital examination and always with the same result. When

the parts were first removed the vaginal cyst was flaccid and contained very little fluid. After it had been immersed some days in spirit, it became distended with fluid.

SCIRRHUS OF THE RECTUM, LIVER, AND PYLORUS.

Mr. Bindley narrated the following case:—

John Screen, aged 55, of short stature, and spare habit, by trade a bellows-maker; has been a hard-working temperate man, and usually enjoyed good health. A brother about his own age died of phthisis. For some years past has been subject to hæmorrhoids, by which he often lost a good deal of blood, and became considerably reduced in flesh. In the early part of the present year the piles ceased to be a source of inconvenience, and about midsummer he began to complain of uneasiness in the fundament, with a sense of heat, and occasionally shooting pain. His bowels were relaxed, and he often passed bloody mucus with the stool.

On September 11th, 1848, when I first saw him, in addition to his above symptoms, he complained of an almost incessant desire to pass a stool, severe pain preventing sleep, loss of appetite, and flatulency. The tongue was dry and furred, with a red line down the centre; bowels relaxed, the fluid fæces being always mixed with mucus and blood.

On examining the rectum with the finger it was found (from within half an inch of the anus as far as the finger could reach) occupied on all sides by rounded elongated masses, smooth on the surface, and of considerable firmness, between which it passed with difficulty and pain. The mucous membrane was entire, and no blood followed the finger. These scirrhus growths lay in a longitudinal direction, and varied in size from that of a quill to that of the finger. His skin did not present the tint of cancerous cachexia. He was ordered leeches to the anus, hip-bath, morphia at bed time, copaiba, with liquor potassæ. For some time he was relieved.

October 22nd. There is a hard and tender swelling around the anus, indicating the formation of an abscess; the finger would not pass more than an inch into the rectum; scirrhus tumours enlarged, nearly blocking up the passage; has had no evacuation from the bowels for a week; has difficulty in passing urine; pulse 80, and weak; takes but little nourishment; is becoming emaciated; face flushed; extremely irritable. The bowels were with difficulty moved by the *Mistura Sennæ Comp.* The abscess about the anus formed and broke in a few days, its contents consisting of pus, mixed with fæculent matter, thus showing its nature and origin. After this the fæces passed altogether by this fistulous opening beside the anus, and by the establishment of this free passage for the stools, he was for some time considerably relieved, but in a few weeks, by the growth of the scirrhus tumours higher up in the bowels, constipation again ensued. About the end of October the right lobe of the liver was found enlarged, and projecting from beneath the cartilages of the ribs towards the umbilicus; it was indurated, and had an uneven surface, but was not tender. At the same time, in addition to loss of appetite and flatulency, daily vomiting had supervened, the matter ejected consisted at first of food mixed with mucus, but

subsequently had the coffee-grounds character. Tongue dry, and black in the centre. Great thirst.

In the beginning of November the ulcerative process was set up, and there was a great discharge of pus, mixed with blood and mucus.

On November 20th he had had no evacuation from the bowels for ten days; an enema of warm water was thrown up to the extent of three pints, and was followed by so copious a discharge of fluid fæces, as to bring on fatal collapse on the 29th.

Sectio cadaveris forty hours after death. The brain and thoracic organs healthy. The liver rather smaller in size, of firm texture, pale in colour, uneven on its surface, and presenting, when cut into, extensive cancerous degeneration. In the left lobe it was infiltrated throughout; in the right deposited in rounded masses, of various size. The pyloric end of the stomach and commencement of duodenum were drawn up and firmly adherent to the under surface of the liver, in the region of the gall-bladder, of the existence of which no trace could be found. Within the coats of the pylorus was a small mass of scirrhus, partly blocking up the opening. The stomach was greatly distended, and contained two pints of dark coloured fluid, with coffee-grounds deposit. Small intestines, spleen, pancreas, and kidneys, sound, except that the pelvis of the right kidney, and commencement of its ureters, were somewhat dilated. Whole of colon greatly distended, and the transverse arch pushed downwards to the pelvis. In the rectum the disease was limited to its lower half, extending for the length of about six inches from the anus, reaching to the recto vesical fold of peritoneum, but not passing higher. The scirrhus matter is deposited chiefly within the coats of the gut, projecting inwards in the shape of tuberiform masses, of a yellowish grey colour, semi-transparent and glossy; when cut into they exhibit the usual appearances of scirrhus, with the deposit of a softer matter in the meshes of the stroma. Its mucous membrane is ulcerated, the ulcerated opening at one point leading into the cavity of a large abscess, formed within the coats, the walls of which have a sloughy appearance, and communicate with the fistulous aperture by the side of the anus.

ON

LIFE INSURANCE AMONG MEDICAL MEN: PROVIDENT SOCIETIES: ANNUITY & ENDOWMENT INSTITUTIONS: AND THE BENEVOLENT FUND.*

By WILLIAM NEWNHAM, Esq., Farnham.

To those who have been positively unable to avail themselves of any of the preceding methods of relief, or who, from misfortune, have omitted to do so;—to those who have been deprived by sickness, or other temporary difficulties, of the means of earning their own livelihood;—to those whom insanity has deprived of the power of continuing their exertions;—to those families whose main support has been suddenly re-

moved in the earlier part of life, and before provision for the future has been made;—to those whose last penny may have been spent during protracted illness, upon the comforts of him who is “gone before;”—to the destitute orphan—aye, even to him who has kept his mother from starving by manual labour of the severest character;—to those who have suffered cruel privations, and have been exposed to the “whips and scorns of time,” and the neglect and the contumelies of a selfish world;—to all these and many other forms of misery, the Benevolent Fund alone extends its offers of relief, without money and without price,—and pursues its course of unwearied practical benevolence, wherever misery is to be found *which cannot be relieved by other institutions*: a fact which has been shown in a very marked manner during the past year, since in several instances the Benevolent Fund has relieved cases which have been transmitted from the local societies, because by them unreliable.

And yet, strange to say, this institution languishes for want of due support, and is assailed by objections, a few of which I shall now consider.

First,—“It is not required: and except in cases of gross misconduct—of improvidence—of reckless and thoughtless expenditure, every medical man has the opportunity of providing for his family, and of preventing their being left dependent on the world.” Now, what are the facts? Why they are these:—first, that medical men *with families*, are very seldom in a position to make provision for those families, unless they have private fortunes of their own;—that very usually their private fortune has been expended upon their education and first establishment in life;—that it is very unusual, where professional income easily covers professional expenses, and those occasioned by the maintenance and education of children;—that commonly they are poor, and at each year’s end are scarcely level with the world;—and that when they die they leave their families without the means of permanent succour.

But again, what are the facts?—let the history of the last year of the Benevolent Fund tell its own tale, and yet it is to be recollected, that this will reveal only a very small portion of the sum of professional misery. Moreover, this history is taken from the class of regularly educated practitioners only, and is confined to those whose habits of prudence, and providence and sobriety, entitle them to the regard and esteem of the charitable. The Benevolent Fund has relieved during the last year upwards of thirty cases, after due investigation, and it has rejected several others which would not bear the searching test of inquiry. Among these cases so relieved, we have a man most highly respected in his town and county, yet struggling with the “*res augusta domi*,”—assailed by *ramollissement* of the brain—his little all expended during a three years’ illness—dying, leaving a widow and five children—the eldest, only fifteen, who is keeping a little school and earning two shillings a week,—the rest dependent absolutely for bread upon the tender mercies of a Board Guardians. Another is attacked by insanity, and in the prime of life is cut off from his professional income; he has no

private property, and he becomes pauperized. His family are as yet uneducated; one only by her exertions as governess, can contribute to the support of her parents. But how can the scanty earnings of an ill-paid governess support a father and mother and five brothers and sisters, altogether without income? It is notoriously impossible. Another, who has by great exertion just kept his family above the cravings of want, dies in a few days from fever caught in the discharge of his professional duties, and his widow and three children are thrown upon friends; the children are sickly and unable to do anything for themselves; the friends of their father have done something for a time, but except for the interference of the Benevolent Fund the workhouse became their last and only refuge. Another has died and left a widow and five children, all young, and as they could not be educated, they are to be found as they grew up, filling menial offices,—and the youngest boy in order to keep his mother from starvation, has been serving the masons. The widow had been aided some years since, is now dead, and this year her exemplary boy, who had been snatched from his degrading position, and educated partly by the kindness of friends and partly by the aid of the Benevolent Fund, has been rescued from the wearisome prospect of manual labour, and placed in a position to follow his father's profession;—has been apprenticed to a most respectable surgeon, the Fund engaging to give £20 a year for three years, towards this object. These are specimens which occur to my memory at the moment: they are not selected as the worst of their fellows, but are ordinary, every-day examples. Time would fail me to tell one half of the misery which comes before us.

But it is replied, "these things ought not to be." And yet in the nature of things it is impossible to be otherwise. It is very easy for the affluent, and the young, and the healthy, with the buoyancy of life's prospects before them,—with hopes unbroken,—and aspirations not disappointed,—and feelings unchilled by repeated contact with a selfish world;—it is very easy for these, and such as these, in the day dream of imagination, to assert that these things ought not to be! Yet, laying aside all feeling, let us look at the question in a plain practical point of view. First, the profession is overstocked: it is vain to attempt to deny this, because it is proved by the number of candidates to fill up every vacancy, however occasioned. Secondly, when a market is overstocked, whether it be with talent or any other marketable commodity, a depreciating operation is effected upon the commodity so to be disposed of; and the holders of such commodity must be deprived of their profits, compelled to dispose of it at a very trifling gain, perhaps at a frightful loss, or else be irretrievably ruined, because they can get no sale at all. Now, the fact is, that everywhere, except in some few fortunate cases, the remuneration for professional talent has greatly diminished, and every man in some way or other has to submit to this depreciation. Especially is this remarked in every instance of public competition. No sooner is a vacancy advertised in a *Poor-Law Union Surgery*, than numbers

step forward as candidates,—as candidates for what?—even for a position of the deepest responsibility, and for a salary which, if the holder does his duty honestly by the poor, leaves him at the end of the year without a penny, and minus a very considerable proportion of his expenses. And in order to prevent this competition, and the introduction into a neighbourhood of a young new-comer, willing to make any temporary sacrifice to obtain practice, the older and more-established resident medical men yield their services with the conviction of a great loss to be sustained, merely to keep their own circle of patients uninvaded. There can, therefore, be no doubt that the profession is overstocked, and as a necessary consequence what it has to sell is disposed of at less than its proper price, and if so, at a loss; that loss being represented by a certain amount of personal and family privation, which pride and self-respect conceal from the sight of the world. If then the commodity of talent be sold at an unremunerating price, it is clear that the vendor must become impoverished, and that sooner or later he must be involved in pecuniary difficulties. Under these circumstances he gets on difficultly, he is assailed by indisposition, he is unable to continue his laborious exertions, and after a little catching at the straws of the drowning man, he sinks into indigence, and requires aid. And how is this to be avoided? The life of a medical man is proverbially uncertain: he is exposed to a thousand casualties from which others are exempt;—he incurs the risk of infectious malady;—his nights are disturbed often for very long together;—his days are unusually weary, wasted, and worn;—he is exposed to the inclemencies of weather without the possibility of protection, or of putting off his visits till a fine day;—and above all, to the difficulties with which he has to struggle, in the vain effort to do his duty, and to please at the same time. The consequence of this unusual exhaustion is, that his health gives way, and he becomes less capable of attention; by degrees his practice and his means of subsistence decline together, and the end of all is, that he is more and more straitened, and dies in debt, or perhaps is immured within the walls of a prison, and his family are left beggars. Again, he is exposed to the like casualties as others; and he is often ruined by misfortune—by injustice—by the failure of others—by law—by sickness in his family—by a spendthrift son—and by various other causes, all of which legitimately make him poor, and therefore there must in the very nature of things be instances of misery and destitution.

But then it is said, these should have been provided against. How? By Life-Insurance? Of no use till he were dead: and by the supposition, his income has not been such as to pay a life-insurance premium to any available amount. By belonging to a Provident Society? This gives nothing to himself, though it may to his widow and children, and even this in itself would generally be inadequate to their support; and perhaps he may not have been a member long enough to ensure even this pittance,—or his claim may have been forfeited by his being unable to continue his subscription. Instances of these have come before us,

so that here again misery and destitution are inevitable and therefore the *Benevolent Fund* is necessary for their relief, and no other fund is available for such relief.

Again, it has been objected that the existence of this fund is *degrading* to the profession. **DEGRADING!!** It may indeed be *degrading* to the profession to have within its pale many men of very moderate talent,—of very moderate pretensions to gentility,—of very moderate principle,—of very moderate income! It may be *degrading* to the profession to number among its brethren many of the sons and daughters of misfortune,—many who have been disappointed in life,—many who have been harassed by sickness, and poverty, and misery! It may be *degrading* to the profession to find many of its members, whose lives have been cut short by disease contracted during the performance of their duties! It may be *degrading* to the profession to reckon among its members many who have been assailed by insanity, and whose brains, never strong, have been overturned by the constant stress laid upon that organ! It may be *degrading* to the profession to find many victims of phthisis, or some other of the almost innumerable forms of hereditary scrofula! It may be *degrading* to the profession to leave widows and orphans unprovided for and penniless, cast upon the wide world without one ray of hope, obliged to seek succour in menial employment, or to fly their native land! These and many other forms of existing misery may be *degrading* to the profession; but it is yet more *degrading* to acknowledge their existence and not to endeavour to relieve them. To pass by,—to say, be ye filled, and clothed, and warmed, and not to supply the means for satisfying hunger, and cold, and nakedness,—this is *degrading*! To turn away from the cry of the widow and the orphan,—to turn a deaf ear to the voice of him who is ready to perish,—this is *degrading*! To admit the evil and not to stretch out the hand to relieve it,—this is *degrading*!—or else it is degrading to feed the hungry,—to give drink to the thirsty,—to shelter the houseless wanderer,—to clothe the naked,—to visit the sick,—to release the prisoner,—to imitate our first and highest example—HIM who spent a life of love to man, in going about binding up the broken hearted, and healing every manner of sickness, and sorrow, and infirmity!

But further the principle is objected to. It is said that “where a certain sum is to be given away in charity, a certain amount of good must be the consequence; but it is wrong in principle, because it encourages dependence.” At every turn we meet with this objection, which is tantamount to saying—poverty induced by misfortune is a crime, and should be visited by punishment, not by relief, for relief increases the evil, and multiplies the claimants. This is a very fashionable objection, and is borrowed from the argumentation so often heard at the pay-table of Poor-Law Guardians. We will say nothing of the folly of insisting that persons who have not sufficient for the year's expenses should be capable of accumulating for a rainy day. We know it would be quite right if they had the means, but they have not. But it is

objected that by our Benevolent Fund we take away the stimulus to economy, because parties know they can have relief if they get into difficulties, and are left destitute! They know it not: for, first, our relief is always inadequate to their daily necessities; it is precarious, because dependent upon the will of a committee, and the state of the funds at their disposal, and is never permanent, therefore can never be relied upon, and can never be said, even by the ultra-economists, to *create* distress. There is, in fact, no serious belief that it does *create* distress, but the argument may be useful among the other arts of evading a charitable subscription.

Again, these things are best managed by local funds, such as are already established, and not by a general fund, as if a system of favouritism or prejudice were not more likely to operate in a small circle of personal connection, than in the larger sphere, without personal connection, and where every case must be decided upon its own merits. Besides, the astounding fact that several cases have been sent to us by the local societies, inasmuch as they were unable to relieve them, because they were not members, and inasmuch as the investigation of every case is carried on, and sometimes at considerable difficulty, through local residents.

The real truth is, that there is no solid objection against the Benevolent Fund, and parties are aware that there is none, and that every objection may be traced back to its origin, in a real disinclination to give; and therefore, in concluding this paper, it behoves me to call on all my brethren to support this purely charitable institution, which languishes for want of funds.

And since it has been proven that the misery which it professes to relieve is inevitable, and must exist in the nature of things, it follows that it ought to be relieved. No, says an objector, the misery has been self created, and therefore should not be relieved. But first, we assert that we do not knowingly relieve cases which have resulted from improvidence and immoral habits; our object is to relieve the distress of misfortune, not of vice, and we are particularly careful on this point. But admitting (which I do not know,) that we may have been occasionally deceived, and that we may have relieved miseries which owed their *origin* to vice, and which in their consequences have fallen upon others not partakers in this vice, is this a sufficient ground for neglecting the ninety-and-nine cases of pure and inevitable misfortune, because in the one-hundredth the *victims* of the indiscretion of one have been relieved? Do unto others as you would be done by is the Christian law, and let us apply it. Suppose that we are called to patients suffering from dyspepsia, arising from their own want of care,—or to delirium tremens, from excess in alcoholic beverage,—or to syphilis,—or to any other of the thousand ills which flesh is heir to, and which are self-created, are we to stand by and refuse our aid, because the parties have been the authors of their own misfortunes? Such a position is clearly untenable, and the only difference is, that in one case *we pay*, in the other case *we are paid*, to relieve the distresses of others. As medical men this is our

manifest duty and mission; and O! let us not steel our hearts, and lock up the bowels of our compassion, and throw away as valueless the blessing of him that was ready to perish, simply because he is *our brother*, and refuse to him, our brother, an amount of aid which we should often proffer to a street beggar. I am almost ashamed to mention, in such a conjunction, *one penny* a week; yet a penny a week, or five shillings a year, from each one of our members, would give us an income of at least £500 a year; and it must not be pretended, that we are unable to give five shillings a year, or little more than a penny a week, to such an object. Let this be the *minimum*, and let each one give more if he can, according to his ability or inclination. If each one would look upon this act of charity as a *duty*, and really not a matter of choice, and let a larger or smaller sum be forthcoming from every pocket, and many a widows heart would sing for joy,—many a spiritless orphan would be gladdened by the smile of sympathy,—many a cheerless hearth of desolation would be irradiated by the gleam of hope,—and many a wasted spirit would again glow with vitality, from feeling that it was not an outcast because it was poor, and would be comforted by the conviction that its sorrows were soothed, and sought to be alleviated. Let me intreat my brethren to think on these things,—to “hearken and do,”—and to strengthen the Committee by the principled assurance that they would do what they could to support their self-denying exertions.

Yet perhaps it may be said by many, that they have insured their own lives,—or purchased annuities for their widows,—or endowed their children,—or belonged to a local provident institution,—or to a general annuity fund; and if so, they have done well, they have protected themselves and their families, *quoad hoc*, to a certain extent from want. All this is good, and is an offset from that provident charity which *begins at home, but does not end there*, for if so it is not of the nature of that heaven-born charity which “seeketh not her own.” You have provided for yourselves, and this is the strongest motive and argument for providing also for the distresses of those who have been unable to be thus provident, and to lay up treasures for themselves so that thus in aiding others, *you* may be providing for yourselves “treasures in heaven where neither rust nor moth doth corrupt.” If you yourselves are free from the fear of want, O listen to the cry of the destitute,—that feeble cry which is too frequently stifled by feelings of a most time-honoured description, and which has so often to be revealed by the kind detective hand of some neighbour friend. O listen to the feeble accents of grief unspeakable:—

“O give relief, and Heaven shall bless your store.”

WILLIAM NEWNHAM,

Hon. Treasurer and Secretary.

Farnham, March 22, 1849.

P.S.—I am quite aware of the great advantage it would be to the Fund, to publish in detail the cases relieved. But how dare we draw aside the veil of that “sacra miseria,” which courts the shroud of obscurity and shuns the sunshine of observation. How dare

we with the feelings of gentlemen upon our own hearts, expose to common gaze the sorrows of the riven bosom, and the penury and starvation of the solitary garret, and the weariness of that widowed heart, which contemplates with anguish inexpressible the innocent faces of thoughtless children, as yet unconscious of all the asperities of a selfish world.

To this appeal it is right to append the fact, that two important cases will come before the Committee on Tuesday; but that we have so largely anticipated our income, it can scarcely be prudent to relieve them, unless we can rely upon an extension of support from our friends.

W. N.

General Retrospect.

ANATOMY.

ON THE STRUCTURE OF THE SYNOVIAL MEMBRANE COVERING THE SURFACE OF ADULT ARTICULAR CARTILAGE.

Mr. Toynbee has recently published the results of some researches which are confirmative of the opinion advocated by Sir Benjamin Brodie, that the synovial membrane invests the entire surface of articular cartilage during all periods of life, so long as the cartilage is in a healthy state. The methods by which the presence of the synovial membrane can be displayed are the following:—“If the synovial membrane which surrounds the border of adult articular cartilage be traced to the margin of the latter, it will be found to adhere very firmly, and should an attempt be made to tear it from the surface of the cartilage, it will often give way; in some parts, however, and that not unfrequently, a continuation of this synovial membrane will be separated by laceration in the form of a thin transparent layer, from the surface of the cartilage to the extent of several lines. Another mode of shewing the presence of this delicate tissue on the surface of articular cartilage is, to make a very thin flap of the latter parallel with its surface, and then by means of a pair of broad-pointed forceps, to draw it gently but firmly in the same direction as that of the section. As a general result of this process it will be found that a layer of transparent membrane varying from two lines to half an inch in length will peel from the cartilage. A third way of demonstrating the existence of this membrane is to place a portion of articular cartilage under water, and to scratch its surface with the sharp point of a firm needle, till a fine membrane is observed to be lacerated, under which the needle may be introduced, and by careful manipulation, the adhesions between it and the cartilage may be broken and considerable portions detached.” In reference to the structure of this membrane, Mr. Toynbee says: “When examined by a magnifying power of 500 diameters, portions which have not been subject to much pressure present the appearance of compressed areolar tissue; portions from the central part of the cartilage are translucent, and have a nearly homogeneous structure; they present on their inner surface numerous fine

points, which appear to be particles of cellular tissue, which have been lacerated in the process of separation from the cartilage; sometimes the inner surface of this membrane presents shallow depressions, which correspond in size and shape with the corpuscles of articular cartilage over which they have been placed and against which they have been firmly compressed; not unfrequently some cartilage cells are seen adherent to the inner surface of the membrane.* Mr. Toynbee adds, "That this membrane is not a layer of cartilage seems evident from the fact that it contains no corpuscles, from its extreme and yet uniform softness and tenuity, the latter being so great that the membrane folds upon itself when floating in a drop or two of water, from the facility with which it is separated from the surface of the cartilage without using any cutting instrument, and from the circumstance that it is visibly continuous with the synovial membrane around the joint. The only fact which seems to militate against its being considered as synovial membrane is the absence from its surface of epithelial cells. The absence of the epithelial layer may, however, be accounted for, perhaps, from the fact, that it is not like the reflex synovial membrane—a secreting organ, and from its being subjected to great pressure."—*London Journal of Medicine*.

PRACTICAL MEDICINE.

CHOREA SUCCESSFULLY TREATED BY ARSENIC.

A case of this kind occurred recently in the clinique of M. Guersant. The practice is derived from the testimony of the profession in this country, and has also been extensively employed in Germany. M. Homberg regards it as the most effective of any of the medicines recently given, and finds it often succeed where others have entirely failed. Some of his cases are given below:—

CASE 1.—A little girl aged 11, had been affected with chorea for eight years, which had resisted a variety of modes of treatment. On the 22nd of Nov. she commenced Fowler's solution in small doses, and in three months was completely cured.

CASE 2.—A case of chorea caused by fright, in a girl ten years of age, and of two years' duration. Jan. 29th 1844, commenced the arsenical treatment, cured by the 5th of May.

CASE 3.—A girl aged 12, was the subject of chorea three years previously, and had a relapse in 1843. Purgatives and carbonate of iron failing to produce any amelioration of the symptoms, arsenic was given and found successful in a very few days.

The dose for a young child should not exceed two drops of Fowler's solution to commence with.—*Casper's Wochensh.*—*Encycl. Med.*, December.

BREAD FOR DIABETIC PATIENTS.

Dr. Percy gives the following recipe:—Take the ligneous matter of sixteen pounds of potatoes washed

free from starch, three-quarters of a pound of mutton suet, half a pound of fresh butter, twelve eggs, half an ounce of carbonate of soda, and two ounces of dilute hydrochloric acid. This quantity to be divided into eight cakes, and in a quick oven baked until nicely browned. At first gum-arabic in sensible quantity was also introduced into this bread, on the ground of the assertion of Professor Graham, that when that substance is taken by the diabetic patient, the proportion of sugar evolved from his system is not thereby increased, and that consequently it might probably supply matter for pulmonary oxidation. However, it was found that it rendered the bread tenacious and disagreeable; so that its use was subsequently abandoned. I wish it to be understood that whatever merit there may be in the production of this bread, it is entirely due to Mr. C. F. Palmer. My friend Dr. Evans suggests, and I think with reason, that this bread would probably be improved by the addition of a certain proportion of bran. Some gluten might also be added with advantage.—*Chemical Gazette*.

SURGERY.

GUN-SHOT WOUND: BALL OPENING THE GRAVID UTERUS: DEATH IN TWENTY HOURS.

At 1 o'clock a.m., March 20th, 1838, Dr. Eve, Professor of Surgery in the Medical College of Georgia, was called up to see Charlotte, a negro girl aged 19 years, said to have been accidentally shot. On arriving he found Dr. R. in attendance, and learned that the patient had just received a pistol ball at the distance of about six paces. She was engaged with a large dancing party when interrupted by the accident. She was standing near the fire-place at the time. The ball entered just above the anterior superior spinous process of the ileum, and penetrated transversely the hypogastric region. The probe and finger could follow in its track, without, however, ascertaining where it had lodged, or whether it had opened the abdomen. There was no external hæmorrhage nor intestinal protrusion. Besides the shock to the general system, there were no special symptoms beyond the ordinary appearance of a gun-shot wound. Upon inquiry he learned that Charlotte was about the fourth month of utero-gestation. At four o'clock a loop of the bowels protruded through the external wound, which was immediately returned by the taxis, and then retained by compress and bandage. The patient now exhibited symptoms of prostration, which continued to increase, notwithstanding the means employed to counteract them, and she died at 8 p.m.,—twenty hours after she was shot.

Early the next morning, March 21st, in presence of the Medical Class, the abdomen was laid open by a crucial incision. About half a gallon of clotted blood was removed from the pelvis, and a small *fœtus* with its *secundines*. The ball was found to have penetrated the abdominal parietes, passing through two or three convolutions of the small intestines; it then made a large ragged opening into the uterus at the fundus. The direction was transversely across the hypogastrium, and from the bone downwards.—*Philadelphia Examiner*.

* These appearances are given in wood-cuts published with the original paper.

HÆMORRHAGE FROM THE TONGUE SUCCESSFULLY TREATED WITH TINCTURE OF MATICO.

October 9th, 1847. W. B., fruiterer, aged 34 years, states that on the 6th instant he received a blow upon the chin, whilst the tongue was protruding from the mouth, which caused that organ to be wounded by the teeth. Hæmorrhage followed, so copious and uncontrollable, as to render it necessary to apply for surgical assistance. After many unsuccessful attempts to suppress the bleeding, for three days, by several surgeons, he was brought to this hospital in a very weak state, and placed under the care of Mr. Luke. The wound was at first rubbed over with a piece of the nitrate of silver, but the bleeding still continued. A saturated solution of alum was then applied by means of pieces of lint, but still without success; and at last the tincture of matico was had recourse to, and used in the same way as the solution of alum. Fortunately it had the desired effect of arresting the hæmorrhage permanently.

The patient states, that whenever bleeding from the nose had taken place it had generally continued for several days; also that when he was once bled from the arm it was found very difficult to stop the blood, which oozed through the compress and bandage for nearly four days. He further states that he was a patient in this hospital some years ago, on account of hæmorrhage from the urethra, which continued for the space of seven days, and was at last stopped by keeping a large catheter for a long time in the urethra. He was also, it appears, at another time in this hospital, in consequence of having received a wound on his hand, which bled for several days, notwithstanding continual pressure was kept up by compresses, thus showing a very strong hæmorrhagic diathesis. On inquiry, it is found that all the members of his family have the same hæmorrhagic disposition, particularly his father.

The patient, after having been one week in the hospital, without any return of the hæmorrhage, was discharged, with directions to take tonic medicines, and to use such other means as would be likely to have a tendency to strengthen his constitution and improve his general health.—*Lancet*.

OBSTETRIC MEDICINE.

DR. SIMPSON'S AIR-TRACTOR.

The merit of the application of Dr. Arnot's suggestion has been disputed by a Dr. Mitchell, a former pupil of Dr. Simpson's. This gentleman affirms that Dr. Simpson, in mentioning the subject to his class, made certain observations inviting his pupils to test their ingenuity in manufacturing an instrument, and that he accordingly gave his attention to it, and eventually perfected an apparatus, which he described and illustrated by diagrams in his answer to the questions brought before him during his examination for his degree. His complaint is, that Dr. Simpson, though he paid no attention to these remarks at the time, did in fact make use of them to bring out at a future period the discovery as his own. In reply Dr. Simpson disavows any acquaintance with Dr. Mitchell's written

answers, alleging that from his engagements he was in the habit of delegating the office of examiner to others.—*Medical Gazette*.

[Mr. James, of Exeter, also writes to the effect, that the idea had occurred to him prior to Dr. Simpson's announcement, and that he had recorded it in his private notes, but had not made it public.]

NEW TRACTOR VECTIS.

Under this title, Mr. Ogden describes an instrument, the superiority of which consists in its being used as an extractor, and not as a lever of the first kind, on which latter principle the forceps partly, and the lever wholly, acts. On this account it is less liable to injure the mother and child than ordinary instruments. In appearance it much resembles one leg of the forceps, excepting that the curve is sharper, and the oval ring or fenestra is so shaped as to allow of a secure hold on the chin or occiput. The oblong diameter of the fenestrum is 1 7-8ths of an inch, and the transverse, 1 1-8th of an inch. The rim encircling this is of uniform thickness, and 3-8ths of an inch wide. The mode of applying the vectis in a natural presentation is to introduce it with the convex side towards the hollow of the sacrum, and when arrested by the contact of the curve with the promontory, it is to be carried under the ramus of the ischium to the right or left, as the case may require, pushing forward the instrument in the axis of the ear, and raising the handle, when the curve adapts itself to the chin, and receiving it into its fenestrum, becomes placed in a line from the ear to the vertex.

Mr. Ogden states that he has accomplished delivery with this instrument in several cases of contracted pelvis, and in others where in previous labours craniotomy had been required.—*Obstetric Record*, Feb. 1st, 1849.

MEDICAL REFORM.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

I am an old man—long in practice as a surgeon-apothecary—whose humble aspirations have been sufficiently gratified by the position and emoluments resulting from a quiet discharge of professional duties. I have turned with disgust from the violence of medical factions—their publications, their speeches, “full of sound and fury, signifying nothing” to convince me that the changes they advocate would produce the slightest good.

I may be fastidious: but I dislike exceedingly the new designation of “General Practitioners;” a term of equivocal import, that admits of constructions much at variance with the fancied dignity of the gentlemen who assume it. Why do they reject the ancient appellation? All art is honourable; and “the art of the apothecary” is, indeed, time-honored. Above three thousand years ago it was mentioned by the Jewish legislator. It was then an important part of the boasted “learning of the Egyptians.” In our day it cannot *always* be separated from the practice of medicine. The detection of disease and the adminis-

tration of remedies must be associated—at least in rural districts. I have little sympathy with certain fine gentlemen who affect to despise this form of practice, or desire to rid themselves of the name by which it is indicated.

Alas! Sir, "men would be angels;" and a morbid feeling of this sort has vitiated much that was sterling in society. Among agriculturists, where is now the genuine yeoman, who "owed vassalage to no man?" Aspiring to gentility, he clung to a rope of sand; and afforded, as some medical reformers may yet do, melancholy proof that "pride goeth before destruction."

Now, I am quite satisfied with things as they are, and cannot understand what is meant by your correspondent "On Medical Reform" in your last number, when he says, "a vast amount of insult and degradation" has been heaped on provincial surgeons. On occasional visits to the metropolis, I find my way to the College, look over the museum, spend hours in the library, and attend lectures gratuitously. Setting aside the qualification for practice, I deem these advantages cheaply obtained by the twenty-two pounds paid some forty years back for my diploma.

Even the newly created dignity is open to me, notwithstanding my connection with pharmacy. I can rub up a little, and claim examination, but I desire not this for myself; I consider it valueless to the generation with which it originated, though highly important to the next. The education of my sons might have stopped short of University degrees, but for the stimulus of the new charter.

I do not murmur at my own non-election: nothing has been taken from me. I live for my family, and hope they will realize the advantages intended for a higher order of surgeons.

The agitation of the *soi-disant* NATIONAL Institute, as well as that of the party recently sprung up against it, appears to me pregnant with mischief. We have all the protection we require.

I admit the temperate tone of your own articles, and believe that a large majority (the calm and considerate portion) of the members of our Association, find "a head and a home" in existing institutions.

I remain, Sir,

Yours very respectfully,

March 28, 1849.

A QUIET MAN.

PROSECUTIONS BY THE SOCIETY OF APOTHECARIES.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

I have very often heard it said, and also have frequently seen it in print, that the Apothecaries' Company would not prosecute any party holding a diploma or degree from any College or University, whether English, Irish, Scotch, or Continental, I want to know by whom the illiberal prosecution in the unfortunate Dr. Lobo's case was brought, whether by the Apothecaries' Company, or the rich and powerful Medical Protection Society, (who have, or are said to have, mustered some 800 members out of 30,000,) or some private party; I think it very illiberal indeed to select a poor foreign medical man, when (taking the most favourable view you

can,) there are at the very least twenty practising druggists to one illegal medical practitioner at the present time; and if the profession want to do any good, stop at once the druggist from prescribing, by a prosecution, and then you will really benefit the medical profession, for the druggists, and druggists alone, spoil half the practice of both London and provincial medical men. There are at present numbers of surgeons with only the College diploma, compounding all their own prescriptions; also numbers of Edinburgh physicians doing the same; and why, I ask, select a gentleman with a foreign degree, when that diploma was obtained after a most strict examination, quite as much so as the examinations here? Why differ one with another of the same profession, when by only stopping the prescribing of druggists, you will at once give an increased good practice to all?

I am Sir, yours &c.,

A CONSTANT READER AND LIBERAL
MEMBER OF THE PROFESSION.

LIFE ASSURANCE OFFICES.

REMUNERATION OF MEDICAL MEN FOR THEIR REPORTS.

In the list of Life Assurance Offices which have adopted the principle of remunerating medical men for their reports, as given in the last number of this Journal, the London and Provincial Joint Stock Life Insurance Company, 39, Nicholas Lane, London, which started originally on that principle, was accidentally omitted.

ROYAL COLLEGE OF PHYSICIANS.

Gentlemen admitted Licentiates Monday, April 2nd:—Francis Sibson, M.D., London; Augustus Henry Novelli, M.B., Cambridge; John Augustus Tulk, M.A., Cambridge.

SOCIETY OF APOTHECARIES.

Gentlemen admitted Licentiates Thursday, March 29th:—Frederick Charles Spackman, Bradford, Wilts; George Bullen, Ipswich; Johnson Kaye Baines, London; John Sherwood Stocker, London; John Moore Swain, Long Clawson.

OBITUARY.

March 15th, at Clapham, Surrey, aged 29, Walter Yonge, M.D.

April 1st, at Liverpool, aged 30, Edward Dunn, Esq., Surgeon, Ulverston.

TO CORRESPONDENTS.

Communications have been received from Mr. H. Williams; the Birmingham Pathological Society; a Constant Reader, &c.; Dr. Ballard; Mr. C. Anderton; Mr. R. King.

We regret that our arrangements did not admit of the insertion of the Petition of the Convention of Poor-Law Medical Officers this week; the petition will appear in the next number.

PROVINCIAL MEDICAL & SURGICAL JOURNAL.

A COURSE OF LECTURES ON SURGERY,

DELIVERED IN THE
MEDICAL SCHOOL OF CAMBRIDGE.

By GEORGE MURRAY HUMPHRY, Esq., Downing
College, Surgeon to Addenbrooke's Hospital.

LECTURE VII.

SUPPURATION AND ABSCESS CONTINUED: HECTIC FEVER.

Treatment of Chronic Abscesses; Means calculated to effect their disappearance without bursting; Artificial opening, valvular, by Trocar; Inflammation of lining membrane; Abscesses of long standing best removed by the Knife; Simultaneous occurrence of Abscesses in various parts of the body, arising.—first, from depressed condition of a part, or of the system, which may have been caused by severe Accident or Operation, or from Cachectic state; Treatment of these Cases;—secondly, from admixture with the Blood of Pus, or other Morbid Matters, occasioned by Traumatic Inflammation of a Vein; Spontaneous Phlebitis not inducing these results.—Hectic Fever; Conditions under which it occurs; Symptoms; Chill, Fever, Perspirations, their relation to one another, and to the general cause; Treatment.

The treatment of chronic abscesses involves many considerations, of which we can now enter only upon a few. I have already mentioned that they occasionally disappear without bursting. This fortunate event is most likely to take place in those very cases in which the abscesses prove most troublesome to heal, if they burst or are opened,—viz., in abscesses occurring in scrofulous or delicate persons, and in abscesses connected with disease of bone, especially if that disease be of syphilitic origin. You know how fatal are psos and lumbar abscesses connected with caries of the vertebral column, when they burst; it is therefore well to bear in mind, that these abscesses sometimes disappear, or remain stationary, for a great length of time. I have seen a few well-marked cases in which the swelling gradually subsided, the spine seemed to become sound again, and the patient recovered his health, although there had been no doubt of the existence of an abscess, and the abscess had been attended, or rather preceded, by the usual signs of vertebral disease. Moreover, in the examination of the bodies of patients who have suffered from disease

of spine, it is no uncommon thing to find the remains of abscesses, which may or may not have proceeded to such an extent as to have presented externally, leaving the appearance of being in a dormant or retiring state. Their walls are, in such cases, thick and tough, and their contents are creamy, putty-like, or even calcareous; we have, therefore, a double reason to beware of interfering with psos and lumbar abscesses; their fatality when they are opened, and the fact of their occasional spontaneous disappearance. The same remark applies to chronic abscesses in general, and particularly to those which occur in delicate subjects, or which are connected with disease of bone in any situation; they are all very slow to heal when opened, and their contents occasionally are removed by absorption. We cannot indeed look forward to this result with any degree of certainty in particular cases, but we should not forget to regard it as a possible event.

The treatment which has appeared to me most favourable to the disappearance of chronic abscesses, has been such as is most conducive to the general health,—exercise in the open air, nutritious diet, cold ablutions, and tonic medicines, together with some mild irritant to the skin covering or near to the abscess,—the application of tincture of iodine, or what is still better, a succession of small blisters. The disappearance of the vertebral abscesses to which I have referred took place in each instance while the patient was allowed to walk about and attend at the hospital occasionally. One of the men followed his avocation as a day labourer during nearly the whole time that he was under treatment. I think the more delicate and scrofulous class of patients who suffer from vertebral abscess have a better chance of obtaining a cure, by the absorption of the pus and the retiring of the abscess, than stronger and healthier persons, in whom the disease is of more accidental nature. The effect of iodide of potassium, and occasionally small doses of mercury, in promoting the disappearance of abscesses depending upon syphilitic disease of bones, is very decided. There are frequently to be seen in attendance, at the out-patient's room, delicate persons with chronic subcutaneous abscesses, unconnected with disease of bone, which are in process of absorption, under measures directed to the improvement of the general health, together with local stimulating applications.

The same general rules apply to the opening of chronic abscesses, which I laid down in the last

lecture, when speaking of the treatment of acute abscesses. The natural opening affords the most favourable vent for the matter, but it is not advisable to allow the skin to become much undermined, especially in the chronic subcutaneous abscess, for these are very liable to be followed by troublesome sinuses and ugly cicatrices, which may often be prevented by a timely incision. As a general rule, subcutaneous chronic abscesses should be opened as soon as the integuments over them begin to be discoloured, for the chance of their disappearance, without bursting, after that has occurred, is very slight. The opening should be free, and care taken not to injure the walls of the abscess by rough manipulation. It may be remarked that chronic abscesses, being accompanied by little inflammation, are in their progress more subject to the influence of gravity, and the mechanical effects of the pressure of their contents, than acute abscesses; they therefore approach the surface of the body less directly, and often travel to a considerable distance without bursting. This disposition to extend in the direction of gravity does not generally furnish a sufficient reason for opening them, because their progress is not attended with much injury to the surrounding parts. We not uncommonly see patients with large abscesses extending from the loins to near the knee, who are able to walk about, and do not appear to suffer much inconvenience.

In the case of a large chronic abscess, which is steadily increasing, and bids fair to approach the surface and burst, we sometimes endeavour to effect a compromise by evacuating a certain quantity of the contents, allow the wound to heal, and trust that the remainder may become absorbed, or that the matter may re-accumulate more slowly. With this view an oblique or valvular incision is made into the abscess, as recommended by Mr. Abernethy; or, (and this plan generally answers better,) the integuments having been divided with the knife, a trocar is introduced obliquely into the abscess. I have adopted this treatment in several instances, and have not seen any ill consequences result from it, but I have generally found that after the operation has been repeated two or three times, the wound does not heal, or the cicatrix gives way, and the abscess takes much the same course as if it had been allowed to burst: occasionally, no doubt, the treatment is more successful. Some of you may remember the man in Maynard's ward, with a large psoas abscess, preceded by the usual signs of vertebral disease, which I tapped with a trocar three times, at intervals of about two months. On the first occasion two pints of pus were evacuated; on the second, a pint only; and on the third, which is three years ago, half a pint of thin fluid was discharged, more nearly resembling serum than pus. After this the fluid re-accumulated a little, but I did not think it advisable again to remove it; the man, therefore, went home, and I learn from his friends that the swelling by degrees disappeared entirely, some weakness in the loins being the only remaining symptom of the disease.

When an abscess has begun to point, or rather, when the integuments at the pointing spot are discoloured,

you cannot prevent the formation of a permanent opening at the part by an incision, or by the use of the trocar; for if an incision be made where the skin is discoloured, the wound will not heal; and if it be made at a distance from the pointing spot, the evacuation of the contents of the abscess in this manner, by a side-door, as it were, will not prevent—will scarcely even retard, its bursting, where it had begun to point. Nevertheless, the artificial opening does no harm, and I think it in some measure diminishes the shock to the system, which is occasioned by the bursting of a large abscess, and the sudden discharge of its contents.

The treatment which I generally adopt in cases of large chronic abscess, connected with disease of bone, such as psoas abscesses, is as follows,—first, I endeavour to promote the absorption of the pus by counter-irritants; I direct issues to be made near the diseased bones, or small blisters to be applied in the neighbourhood of the abscess. The patient is at the same time allowed to go out of doors, if he can do so, and a moderately nutritious diet is given. If, in spite of these precautions, the abscess continues to advance, and to approach the surface, so as to render it probable that it will soon burst, I draw off some of the pus by a trocar, keep the patient quiet for a few days, and then allow him to move about again. The operation is repeated according to circumstances. When the abscess bursts, which generally takes place sooner or later, the patient is induced to get up and move about with crutches, as long as he is able to do so, the limb on the affected side being rested in a sling. By these means the progress of the disease is certainly, for the most part, delayed in its several stages, the hectic period is averted for a time, and an increased opportunity afforded to the constitutional powers of the patient to withstand the enervating effects of the disease, and to carry on the reparative processes necessary for a cure.

It may seem strange to talk of the inflammation of an abscess, but the membrane lining the cavity not unfrequently becomes inflamed after an opening has been established whether by natural or artificial means: more particularly when the abscess is of large size, and when the matter has been roughly squeezed out of it. The part becomes very tender and painful, the discharge scanty, thin, fetid and mixed with blood. The accompanying constitutional disturbance is sometimes severe, the fever being rather of an asthenic character, the pulse very quick, perhaps intermitting, the tongue dry, the skin hot and dry, and the patient restless. Under these circumstances it is important that the opening be sufficiently large to permit the free escape of the new irritating products formed in the interior of the abscess, and much relief is often afforded by enlarging the opening. At the same time warm fomentations or poultices should be applied to the part, and general antiphlogistic treatment adopted, not bloodletting, but antimonials, saline aperients, &c. This train of symptoms sometimes follows the admission of air into the abscess, which causes decomposition of the pus and irritates the lining membrane; but it is more often induced by the escape of blood, which, mixing with the pus, undergoes decomposition and

gives rise to the dirty fetid fluid discharged on these occasions. The effusion of blood may be caused by abrasion of the lining membrane of the abscess, and it is most likely to take place when the patient is much out of health at the time the abscess bursts or is opened. It may be expected, and its ill consequences may be watched for, when the matter which first escapes is stained with blood. In the case now in the hospital, where so much swelling of the limb, with severe constitutional disturbance followed the removal of the contents of a large deep abscess in the thigh, the man was in a wretched state of health at the time, and the fluid which flowed through the opening was thin and of a reddish colour. You remember what immediate relief was after two or three days afforded by a free incision into the abscess, giving vent to a large quantity of dark grumous stuff, which stunk like the contents of a filthy drain.

With regard to the treatment of those abscesses of long standing which are often mistaken for tumours, I believe it is the best plan to dissect them away altogether, provided they be free from connection with great vessels and other important parts, because their walls are often of considerable thickness, and they are lined by a structure resembling mucous membrane, so that they do not granulate freely and heal kindly when they are opened, but sometimes remain as sinuses for years. Besides, incisions into these abscesses are occasionally followed by troublesome inflammation of the erysipelatous kind, in the same manner as is the opening of serous cysts, bursæ, &c.

I must not omit to say a few words respecting an interesting and important class of cases which have been for some time known to surgeons, and have attracted especial attention of late years in this country. I refer to those abscesses which occur in various parts of the body, often in considerable numbers and usually associated with some primary abscess, ulcer, or local lesion attended with suppuration. They have been called metastatic or sympathetic abscesses, purulent deposits, or by other names according to the views which different writers have entertained of their nature and origin. They form a grave addition to the local disorder; and the constitutional symptoms with which they are attended are always very severe, and for the most part fatal. I need not stop to refute the idea formerly entertained, that they are occasioned by the absorption into the circulatory current, of pus from the primary abscess or ulcer, and its deposit in the new situation, for you are aware that the corpuscles of pus cannot thus readily pass to and fro through the walls of the vessels. As I have just intimated, you will find some difference of opinion respecting the nature of these abscesses. By most modern surgeons they are thought to depend upon the presence of pus in the circulatory system consequent on the inflammation of a vein, but they have appeared to me to take place under two very different circumstances; first, (and this division includes I believe, the greater number of cases,) suppuration takes place in various parts of the body in consequence of an enfeebled and depressed state of the system; secondly, it is sometimes occasioned by pus globules or

other morbid fluids mixed and circulating with the blood.

Let us consider the first class of cases a little in detail. Observe what frequently takes place in a limb which has been severely injured. Suppose a bad compound fracture or dislocation with much bruising, where attempts are made to save the limb, but the case goes on badly. In a day or two the limb becomes swollen and discoloured, thin grumous fluid issues from the wound, the extremity below the injury acquires a livid or dark colour, is cold and loses its vitality. Higher up, the limb assumes a dusky red hue, with more or less heat, indicating a state of low inflammation. If this inflamed part of the limb be examined after a short time, it is found to be loaded with serum, and suppuration is discovered to have taken place in various parts. The pus in some places is collected into distinct cavities lined with lymph, in others it is infiltrated into the cellular tissue, or into the texture of the muscles, dissecting and separating their fibres. There can be no doubt in such a case, that the abscesses and the interstitial suppuration depend upon the direct effects of the injury, extending far beyond the apparent mechanical lesion caused by it. The whole limb received a shock, sufficient to destroy the vitality of its lower part, and to induce a low kind of inflammation which was quickly followed by suppuration higher up. We have had of late years several opportunities of witnessing these symptoms following the severe lesions occasioned by railway carriages passing over and shattering limbs. In several cases where amputation was performed above the apparent seat of the injury, the less directly appreciable effects of the shock upon distant parts of the limb were shown in the sloughing of the stumps and the formation of abscesses at various points in the limb above the amputation. In cases where amputation was performed below the knee on account of injury to the ankle or lower part of the leg by a railway carriage, though the parts cut through appeared to be sound, we found that the stump generally sloughed. Sometimes, in addition, purulent infiltration took place into the limb. At others abscesses formed, although the stump did not slough. In one lad who recovered after amputation performed below the knee on account of severe injury to the foot and ankle, I opened three abscesses which formed consecutively in the thigh, and one in the buttock. Neither of these had connection with each other nor with the stump.

Such abscesses are not of uncommon occurrence in a limb above the point at which amputation has been performed under other circumstances, or indeed in a limb which has been the subject of any severe operation or injury. They do not result merely from the burrowing of matter from the wound, because they are often quite unconnected with it, but they must be regarded as a consequence of the impression or shock occasioned to the limb by the severe lesion of the operation, which, felt in the greatest degree in the line of incision, vibrates through the limb, and more or less through the whole system. Abscesses in a limb after operation are most common when the powers of the patient are low, or when, in addition to that of the

operation, the limb has received some previous severe shock, as in the cases of railway injury just mentioned.

But the shock of an accident or an operation is not generally confined to the injured limb, it extends to the whole system, and the effects of the depressed condition occasioned by it are witnessed in various ways, and, among others, in the liability of different organs to inflammation, which soon runs on to suppuration, or it may be to gangrene. How many persons die of suppurative pneumonia, pleurisy, arachnitis, or hepatitis, after severe accidents, operations, or burns. These secondary inflammations and abscesses are most frequent when the strength of the patient has been much reduced by illness before or after the operation, more particularly when there has been erysipelas or much suppuration in the limb. A man received some injury to the right wrist, from a heavy bar of metal falling upon it, traumatic gangrene set in, and the arm was amputated just below the shoulder on the fourth day. Four days after the operation erysipelas attacked the stump, and spread over the shoulder, chest, back, and loins. On the twenty-third day after the operation, when the erysipelas was subsiding, and the stump doing well, he was attacked with pain in the left shoulder, and in the fingers of the same hand, which was thought to be rheumatic. Then he was seized with pain in the right hip and right side of the chest, attended with occasional severe rigors, followed by profuse sweats. An abscess formed on the shoulder, which was opened, and three or four ounces of fetid bloody pus evacuated, affording some relief to the patient. Attempts were made to support his strength with wine, ammonia, bark, &c., but he became weaker. Two months after the operation the right lower extremity became swollen, tender, and painful. An aphthous state of the mouth with diarrhoea followed, and he died six weeks after the amputation. On *post-mortem* examination the stump was found to have nearly united, and the vein was quite healthy. There was a large abscess beneath the right deltoid muscle, another in the course of the right psoas muscle, communicating with the hip-joint the articular cartilages of which had been almost entirely removed. The right femoral and external iliac veins were distended with coagula mixed in places with pus. The right pleural cavity contained a good deal of lymph and pus, and there were small abscesses in the lower lobe of this lung.

These inflammations of distant parts, more especially of the lungs, quickly proceeding to suppuration, softening, and gangrene, are a very common sequence of operations performed upon patients who have been much reduced by previous disease, indeed they constitute the most frequent cause of death in these cases. The following instance of this kind will be remembered by some of you:—A delicate young man, in a very feeble state of health, to which he had been reduced by severe suppurative disease of the knee-joint, was admitted into the hospital for the purpose of having the limb removed. He determined on submitting to the operation, which we did not feel justified in declining to perform, although we could not recommend it to him. The limb was accordingly amputated, with very little

loss of blood. For a few days the case seemed to be doing well, and we had hopes of his recovery, but on the twelfth day he was chilly and feverish, with dyspnoea, and pain about the chest, shoulders, and back; the dyspnoea increased, his strength quickly failed, and he died on the eighteenth day after the operation. The stump was nearly healed, there was a small abscess beneath the upper flap, but the artery and vein were quite sound. Scattered throughout various parts of both lungs were numerous inflammatory patches, with hepatization, and grey, soft, suppurating spots in the centre of most of them. We cannot suppose that in these and other similar cases the secondary inflammations and abscesses are the consequence of an inflamed state of the veins, because those tubes are often quite healthy, and when they are diseased, they are so, probably as the result of the same general cause which gives rise to the inflammation of other parts than as a primary affection.

A similar train of events to those we have been considering may occur, not only after an operation or injury, but in the course of any long-continued disease when the powers of the patient are much enfeebled. The life of a person suffering under cancerous ulcer, profuse discharge from an abscess or compound fracture, is often unexpectedly terminated by inflammation and suppuration or gangrene of some distant part. Inflammatory affections of the same kind are much uncommon in typhus and other low fevers; the pus formed in such cases is generally ill-conditioned, fetid, mixed with gas, and much relief is afforded by its discharge. It now and then happens that the illness takes this turn from the beginning. A servant girl, aged about 17, in rather a weak state of health, was seized with rigors, followed by severe pain in the arms and knees, which were thought to be rheumatic; the general symptoms assumed a typhoid character, with great prostration of strength and restlessness; the pulse was small and quick; the tongue dry, brown, and cracked; sordes collected on the lips and teeth; dyspnoea ensued, with delirium; the abdomen became tympanitic, the bladder distended, and she died within ten days of the first attack. On examination after death we found yellowish lymph and pus in both knee-joints, in the left shoulder, and in the bursæ beneath the deltoid and at the acromion. There were also numerous deposits of lymph and pus in various parts of the liver and in the lungs, those in the lungs being surrounded by vascular ecchymosed or hepatized condition of the pulmonary tissue. The right pleura was coated with lymph. There was no evidence of a wound or ulcer in this case, and no disease of vein or of the intestines was discovered.

It appears, then, that suppuration, diffused and circumscribed, may take place in various parts of a limb, in consequence of the shock sustained by the limb from severe accident or operation. It may occur in various parts of the body in consequence of a shock sustained by the system, or in consequence of the general powers having been reduced by loss of blood, by erysipelas, or long-continued disease of any kind. Lastly, it may occur in persons out of health, in consequence of some low typhoid peculiarity of the fever which attacks them.

Now, this first class of cases in which suppuration

occurs simultaneously in several parts of the body, in consequence of an enfeebled condition of the patient, has been confounded with that next to be described, because the morbid appearances are, in many respects, similar, and because the inflammation is frequently found to have attacked a vein. But I have already said that the veins may, under such circumstances, be regarded as suffering in common with other organs, not as the source of their distress.

The treatment should consist in endeavours to restore the general tone of the system. The abscesses should, if possible, be opened early, for their contents soon undergo decomposition, and the fetid gases resulting therefrom, pent up in the body, add much to the general distress. During the febrile state which accompanies the early stage of the inflammation of the lungs and other parts under these circumstances, it may be necessary to employ antimonials and saline medicines, or to remove small quantities of blood by cupping or leeching. The local depletion may be advantageously combined with nutritious diet and tonics, when the inflammation is unaccompanied by fever. We cannot often boast of success in the treatment of these formidable cases, but, as a few have recovered, we should not give them up in despair. Much may undoubtedly be done to prevent the occurrence of such disastrous events by attention to the general health of the patient, by not delaying operations till the powers of the system have been too much undermined by the local disease, by care in preventing unnecessary loss of blood during an operation, and by avoiding too lowering a diet afterwards. By closely watching your patients, and attending to the earliest symptoms in suspicious cases, you may sometimes arrest the inflammation in its first stage, and prevent its destructive effects; remember that those destructive effects very quickly ensue, and that the time during which treatment is most likely to avail is very short.

In the second class of cases the purulent formations in various parts of the body appear to depend upon the admission into the circulating current of pus or other morbid fluids which, passing with the blood into the different organs excite inflammation of them. It is probable that the effects of the inflammation thus induced may vary according to the qualities of the noxious fluid circulating with the blood. Dr. Budd, in his treatise on diseases of the liver, adduces cases to prove that the septic agency may be introduced into the blood from a part in a state of gangrene, the noxious matter thus disseminated destroying the vitality of the tissues on which it acts most strongly. The supposition is worth bearing in mind, though the circumstances of the particular cases recorded are perhaps explained equally well by the depressed condition of the patient which accompanies mortification in one organ, rendering him liable to inflammation and mortification in others.

Mr. Arnott and other writers have clearly shewn that the scattered abscesses and inflammations which occur after injuries are occasionally connected with an inflamed state of the vein near the injured part, and depend upon it as their cause. Cases have frequently

occurred in which, during inflammation of a vein caused by the wound in venesection, tying a vein for the cure of varix, or a ligature placed upon the vein after amputation, symptoms have arisen similar to those I have described to attend the occurrence of inflammation and abscesses in various parts from other causes. The patient is seized with a succession of rigors and sweatings; a kind of low typhoid fever ensues, with quick pulse, dry brown tongue, sallow sunken countenance, &c. Dyspnoea, with pains in the joints and limbs occur; and after death, inflammation and suppuration, diffused and circumscribed, are found to have taken place in the lungs, liver, joints, bursae, or other parts. These alarming sequelae of the inflammation of veins are now so well known, that the apprehension of them has led to a discontinuance of many of the operations on veins which were formerly practised. They are supposed to be occasioned by the escape of pus from the inflamed vein into the circulating current. The pus and blood being intermixed flow on together, but the pus globules which are generally larger than the blood-globules, become arrested in the narrow capillary channels, give rise to inflammation, and so occasion the formation of abscesses.

The mode of formation of these abscesses has been illustrated by the experiment of injecting quicksilver into the crural vein of a dog. For the first day or two the animal suffered no inconvenience, but afterwards it became feverish, had cough, difficulty of breathing, and died. On examination, the lungs were found studded with small abscesses, in the centre of each of which was a globule of mercury. The mercury, in the same manner as the pus corpuscles, being arrested in the capillary tubes at various points, became the exciting cause of the inflammation, which was circumscribed around the spots where the irritating substance was detained.

These inflammations and abscesses in distant parts are occasioned almost exclusively, if not quite so, by the phlebitis which follows the wound or injury of a vein. They are very rarely, if ever, the result of the inflammation of a vein arising spontaneously. I cannot tell wherein consists the difference between spontaneous and traumatic phlebitis, which occasions so important a disparity in their effects upon the system. I do not think that the subject of spontaneous inflammation of the veins has attracted so much attention as it deserves, for I am sure it is of more common occurrence than it is generally supposed to be. I have observed it in a considerable number of instances, and under a great variety of circumstances;—in the latter stages of fever, of pleurisy, and of phthisis;—in cancer and in long continued illnesses of various kinds; most frequently in the veins of the lower, but occasionally also in those of the upper, extremities. You have lately seen both femoral veins inflamed in a case of disease of the hip-joint, and in a patient who died with malignant disease of the scrotum. Though a serious addition to an illness, the disease is by no means necessarily a fatal one, for I have known several persons recover completely from it. It occurs most particularly in patients whose strength has been

greatly reduced by any long continued depressing cause; that is to say, it occurs under nearly the same circumstances with the purulent deposits, which I described as constituting the first class of cases of that kind. Hence it is sometimes associated with those abscesses scattered in different parts of the body, which owe their formation to an enfeebled state of the system. They more commonly precede than follow it when they occur in the same person, and as I have already said, do not depend upon it. In the first cases of spontaneous phlebitis which particularly attracted my attention, I was somewhat apprehensive of the terrible consequences of the admission of pus into the circulating fluids, and watched carefully for the symptoms of inflammation of the lungs and other parts; but I have not known these symptoms to follow in a single instance, so that the disease has for some time ceased to be a cause of alarm to me on that account.

I have no remarks to offer to you in reference to the treatment of these secondary abscesses following inflammation of a vein. You must meet the various symptoms as they arise according to circumstances, but the prognosis is always very unfavourable.

I do not know that I can take a better opportunity than the present for speaking to you of hectic fever. Not that it has any necessary relation to the subject we have been considering, but because it is more frequently associated with suppuration, and the continuance of purulent discharge, than with any other kind of disease.

Hectic fever consists of a peculiar train of symptoms occurring in cases of great debility, when the powers of the system have been exhausted by protracted illness, by phthisis, a discharging abscess, or a suppurating joint. It is most marked in the early periods of life, and when the disease under which the patient suffers is attended with suppuration, and much discharge of matter. It is not so constant an attendant on malignant affections, which is probably owing to the fact, that in cases of malignant disease, even in the latter stages of the complaint, there is greater vigor of constitution, less weakness and relaxation of body, than in those diseases where hectic is a more frequent accompaniment.

The symptoms of hectic are observed to take place in the following manner:—The weakened wasted patient, with pale face, and small quick pulse, is easily excited; the face is flushed after meals, during conversation, or on the sudden arrival of a friend; this is noticed more particularly towards the latter part of the day, indeed, it may take place every evening, and may be sufficient to keep the patient awake till past midnight. During this period of excitement the skin is hot and dry, the pulse is quickened, and there is thirst, perhaps delirium at night. Sometimes the febrile excitement thus spontaneously occurring is preceded by a slight chill, but the chill is not usually observed. When the fever begins to subside, the patient falls asleep, and wakes up in an hour or two bathed with perspiration, which appears first, and in greatest quantity, upon the head, neck, and chest. He now feels cold and languid. He falls asleep again to wake in a short time in the same very uncomfortable condition, and this goes on till morning. Perhaps he is fortunate enough to sleep

on till the morning, or the perspirations may not commence till then. The urine passed in the morning, as well as on the previous night, is high-coloured and turbid, from the deposit of lithates.

When the three phenomena of hectic, (the chill, the fever, and the perspiration,) are present, they follow one another in regular order, and stand in the relation of cause and effect, in the same manner as in ague. The hectic fit is then not unlike an attack of ague. In both there are more or less complete intermissions of the symptoms, and both depend upon an enfeebled state of the body. But in hectic the symptoms are less regular in the time of their appearance, and are more easily induced by slight exciting causes. In ague, the chill, the fever, and the sweating, are proportionate to one another; the two latter do not occur unless they are preceded by the former, and the patient is greatly relieved by the sweating during which he feels comfortably warm. In hectic, on the other hand, the chill is generally wanting, the sweating is mostly the predominant symptom, and often takes place profusely without being preceded by either the chill or the fever, so that it clearly has no necessary relation to either of them. When the chill and the fever occur, by further weakening the patient, they predispose him to the sweating, but they do not generally induce it, unless he falls asleep, whereas he often wakes in a perspiration without having felt any preceding fever or chill. Hence we may assume that the relaxed condition of the body induced by sleep stands more nearly in the relation of direct cause to the sweating than does the fever.

Perspirations, then, constitute the leading feature of the hectic state—perspirations occurring at various times, without the ordinary exciting causes, and unaccompanied by a proportionate sense of heat. Now, undue perspiration is generally to be regarded as a symptom of a weakened condition of the frame. The strongest persons perspire least during exertion. The appearance of moisture on the forehead and lips is one of the symptoms of commencing faintness; a cold clammy sweat generally accompanies a prostrate condition of the body, and tells us that the system is labouring under the depressing effects of some shock,—a fright, or a fractured limb; and the continuance of this symptom informs us that some more severe injury has been sustained, from which the vital powers are unable to rally,—a bowel has been ruptured, a lung perforated, or a liver contused. The hectic perspirations result, in like manner, from the enfeebled state of the patient, and take place most especially during the relaxation of sleep. They are to be regarded, therefore, merely as an evidence of weakness, and not as a symptom of any particular kind of disease. They are by no means uncommon during convalescence from illness, and need not, under such circumstances, excite your alarm, or induce you to apprehend that some seeds of mischief are lingering behind. They frequently happen from sheer debility without any apparent local disease, and a tonic regimen, particularly exercise in the open air, in a carriage or on horseback, or residence at the sea side, will, in such cases, generally effect a cure.

The other features of hectic, namely, the chills and fever which sometimes precede the sweating, are, like it, merely indications of a weak state of body; they show that the system is easily depressed, or easily excited. The change of temperature encountered by passing from one room to another is enough to cause a chill, and the reaction from that chill, the slight stimulus of a meal, or the increasing warmth of the body towards evening, may be sufficient in these delicate frames to light up a fever, which, subsiding in a short time, leaves the patient in a state of depression corresponding to the excitement, a state most favourable to the occurrence of sweating. I think that fever precedes the sweating chiefly in cases where, besides the general debility, the system is chafed and fretted by some advancing local disease, such as a phthisical lung, or a suppurating joint. But there is not on that account any need to resort to the somewhat unintelligible Hunterian hypothesis, that "hectic is a sympathy with the operation of an incurable disease, where the constitution is conscious of the inability of a part to effect a cure." We have seen that the most constant symptom of hectic—the sweating, is a common attendant upon extreme debility, in whatever manner induced, a local disease being by no means essential to it; or if a local disease be present, it is not necessarily incurable because hectic supervenes; and the less constant symptoms of hectic—the slight fever, and the preceding chill, may in like manner be attributed to the general weakness; for excitability, no less than the liability to depression, is usually proportionate to debility.

The weak and relaxed state of the frame in which hectic sweats occur is very favourable to suppuration, so that abscesses are often observed to discharge profusely, and tubercles to soften quickly, during this condition. A variety of other affections are also incidental to this state, and sometimes alternate with the perspirations, such as diarrhoea, erysipelas, inflammation of the veins, &c.

The treatment of hectic consists in the employment of various means adapted to promote the general health, and invigorate the system. I need not say that they are frequently unavailing. Our resources have commonly been expended in the endeavour to prop the tottering frame before it gives this indication of its approaching fall. The disposition to fever makes us fearful of the employment of stimulants, because we know that a greater depression, with perspiration, will follow the excitement produced by them, and the administration of tonics is likely to occasion diarrhoea and sickness. Exposure to the air gives cold, and we have little hope of arresting a local disease which has wrought such havoc on the system. These remarks are intended to apply particularly to hectic supervening upon an advancing local disease, for I have already said that hectic, unattended by local disease, or occurring during convalescence will generally yield to tonic regimen and exercise in the open air.

In the early treatment of a local disease which promises to be protracted, and to be attended with hectic, be careful to husband your resources. Do not

begin the administration of tonic medicines, and a more liberal diet, because the patient is likely to become weak, for if measures be taken while the strength remains unbroken they are rather likely to do harm; at any rate, they soon lose their effect, and you have not then this resource to fall back upon when the disease really begins to tell upon the constitution; rather endeavour to maintain the general vigour by the natural tonics, fresh air, and exercise; and when the health shows signs of failing, the judicious employment of quinine and iron will often, for a time at least, avert the threatening evil.

ON THE

MEDICAL AND GENERAL TREATMENT OF LOCAL DISEASE

IN PREFERENCE TO OPERATION.*

By THOMAS HUNT, Esq., M.R.C.S., Bedford Square,
London.

III.—TUMOURS.

The propriety of extirpating morbid growths is a question, the determination of which is often as difficult as it is important. I propose to enquire generally into the circumstances which justify excision, and to point out also the indications which decidedly interdict the interference of manual surgery.

The question embraces a wide field of practice, and includes diseases of various character and seat. Almost every writer has accordingly classified, or at least segregated, these diseases before determining their treatment. I propose rather to speak of them in the mass, regarding them simply as diseases occupying any locality which can be reached by the knife, or by escharotics, deducing the indications of treatment from certain circumstances connected with their history and pathology, which may belong to all or any of them, whatever be their nature or situation. This is the way we treat internal disease. One drug is not good for the brain, another for the lungs, and another for the liver. The condition of an organ in relation to the other organs and to the general circulation, is the question which determines one treatment far more generally than the anatomical position of the organ, or even than its nature, which may consist of inflammation at one period, and effusion, suppuration, or morbid growth at another. It is desirable that this *medical* principle should be brought faithfully to bear on the management of local diseases. The knife and the caustic of the surgeon are but as the drugs of the physician; the propriety of their use is not determined by the nature of the disease, be it scirrhus, fungous, or fibrous, nor by the part or parts affected, but by the state of the general system. There is one grand principle which should never be lost sight of in the prosecution of this momentous enquiry: *the origin or cause of a morbid growth, where it can be satis-*

* Continued from page 544 of last Volume.

factorily ascertained, should have great influence in determining the question of extirpation.

Impaired health is manifestly the cause of a large majority of tumours. When the health is obviously deranged, and especially when it had begun to fail previously to the appearance of the tumour, excision will generally be attended with no advantage whatever; and this indication will have yet more force when the health has become impaired from obvious causes, such as impure air, extremes of temperature, intemperance, excessive fatigue or anxiety, or any other known sources of exhaustion or disease. Hereditary tendency, when its existence can be fairly demonstrated, (not when the fact is only assumed, as is too frequent,) must also be borne in mind.

When disease makes its appearance under these circumstances, no sensible man ever thinks of the knife any more than he thinks of extirpating the kidney in diabetes, or the lung in phthisis. Whether the disease partake of the character of scrofula, cancer, or the many kinds of undefined, and almost nondescript tumours which are met with in daily practice, the first question is, can the health be restored? And this should be attempted first by placing the patient, if possible, *in circumstances favourable to health*. The air, the diet, the employment, the clothing, and the general regimen, are all to be considered in our endeavours to place the patient in a position in which the system may be enabled to right itself, and by restoring healthy action throw off the morbid incubus. It is thus that strumous tumours disappear at the sea side,—it is thus that diseases which have eluded the ordinary appliances of surgery and medicine have yielded to the bold enormities of hydropathic quackery; the change of air and of diet are the real sources of health. Next to the proper regulation of the “non-naturals,” (as they were absurdly called,) comes the question of medical treatment. The stomach and bowels, or the liver, or the skin, or the kidneys, or the uterus, or all of them together, may require a little help from this quarter, and when their functions are rectified, the local disease will commonly yield, but if it still remain persistent or advancing in spite of an *apparent* restoration of the general health, then the question of excision begins to assume a more tangible form. Excision seems desirable, for the purpose of preventing further growth, or the subsequent failure of the health from the pain or irritation of the tumour. *But, will it cure it?*

If the tumour is visibly increasing (the very circumstance which frequently determines the surgeon to operate,) it is very probable indeed that the operation will do harm rather than good; but this question will be more conveniently considered by regarding the circumstance of this supposed case as equivalent to those in which a tumour exists and *grows* without any *previous* or *present* derangement of the health,—that is, when the patient *looks* well, and where the functions are properly performed, and where there is no local external source of irritation or cause of disease. Now here, if the disease can be proved to be purely of local origin, away with it at once. But how can

this be proved? To this it may be replied, that extirpation has sometimes cured such tumours, and for years subsequent to the operation they have not re-appeared. The fact is admitted; but does it follow that the disease had a local origin, and that *therefore* excision should be the *rule of practice*? It appears to me that there is an illusion, or at least a fallacy, in this reasoning, which leads to a great deal of erroneous practice, and this view of the case is supported by facts. Many of these tumours thus extirpated, under circumstances of apparently good health, do return, and often with increased energy, sometimes becoming malignant and destructive to life. A farmer's bailiff had a tumour on the lower lip, which had existed nearly two years, growing slowly, and attended with little pain. His health was apparently excellent, his complexion ruddy, and his habits temperate. I extirpated the tumour, the wound healed in a few days, and an absorbent submaxillary gland, which had become enlarged, was soon reduced to its natural size. The patient left the neighbourhood in a month; five months afterwards I heard that he was dead. The tumour had returned in an active and malignant form, and had rapidly destroyed him. These cases are common—much more common than hospital surgeons are aware of. A patient is operated on in the hospital, leaves it apparently well, and is entered cured, but he dies in the Union in a few months, the tidings of his death never, of course, reaching the ears, either of the operator, or the dresser. “The man is a pauper whom no one knows.”

But if extirpation, as has been admitted, is sometimes successful in these cases, how is this to be reconciled with the theory of a constitutional lesion? Very easily. Many of these tumours are depositions from a process of chronic inflammation, which may be arrested by the repeated application of a few leeches, which being accomplished, the absorbents remove the tumour. The same result may sometimes be obtained by general blood-letting, and a few doses of Plummer's pill. Surely it is not irrational to infer that the operation of excision is often attended with sufficient hæmorrhage to destroy the inflammatory diathesis, and with it the tendency to disease, and that when the bleeding is insufficient for this purpose, or when there is latent cachexia predisposing to morbid action, the disease re-appears. The therapeutic inference is, therefore, upon the whole, in favour of constitutional treatment combined with local, in preference to the scalpel. When these tumours occupy structures subject to the invasion of carcinoma, it is by no means necessary, or even desirable, to entertain the question whether they be cancerous or malignant, nor is it possible, in many cases, to decide the question in the earlier and curable stages; they should be regarded simply as morbid growths, which *may* become malignant, and which can never be safely removed without previously rectifying the general unsoundness which develops them.

When the health is apparently sound, and the tumour is neither painful nor tender, nor progressive in magnitude, it may be inferred that the health is

really good, and that the neighbouring absorbents being habituated to the presence of the tumour, are, so to speak, reconciled to it, and refuse to take it up. In this case it may be removed, but whether by excision, by caustic, or by topical applications of iodine or mercury, may be determined by its seat, in some cases; in others, the plan which will be likely to leave the smallest scar should be adopted.

The existence of a plurality of tumours at a distance from each other, in a similar structure as in both mammae, or even in dissimilar structures, as in the lip and mamma, should always be considered as decisive against an operation. One and the same cause will generally be found to have originated both, and the proper treatment consists in removing the cause, which may be accomplished by rectifying the general disorder of the system. Salines, with the mineral acids, blue pill, sarsaparilla, iodine, and arsenic, are the medicines which will generally be found most efficacious. When the secretions are healthy, and there is no serious failure of the health, arsenic given internally, on a full stomach, and iodine in the form of ointment externally, will often accomplish the slow, but final, absorption, of many of these morbid growths; but the alterative treatment must be modified by the constitution of the patient, and its success will depend much upon the intelligence with which it is adapted to the peculiarities of the case.

There are some tumours which form exceptions to the above rule, their peculiar locality requires peculiar treatment. Tumours in the eyelids for example, often have their commencement in some accidental local cause of irritation, and grow by friction. They should always be removed by the nitrate of silver, *never by the scalpel*. The same may be said of tumours in the inside of the cheeks and other parts, the mechanical movements of which promote their growth. Those pendulous tumours growing from a small neck, called *polypi*, do not generally denote disordered health, but appear to grow from some local or mechanical cause. It is difficult to account for their origin, but their growth may be dependant upon the elasticity of the arteries in the neck of the tumour, which, by pressure on the contiguous veins prevent the free return of the blood distributed to them. Hence they become partially distended, organization gradually proceeding. No one disputes the propriety of tying the neck or twisting them off from their attachments.

There are perhaps a few other cases in which excising may be required. For instance, when it is certain that the health is suffering from the irritation of a tumour, from its pressure on vital or important organs, from its excessive pain, or from any local or mechanical interference with healthy functions. The most difficult cases to decide upon are those in which the health suffers both from an originally malignant taint, and from the constitutional irritation of the local disease. Amputation affords temporary relief in some instances: in the majority it only aggravates the sufferings and precipitates the death of the patient. In Dr. Walsh's invaluable work "On Cancer," he has proved by statistical enquiries that "the chances are, that extirpation either proves fatal at once, or is followed by reproduction of

the disease within twelve months," and that extirpation of cancerous growths by the knife can neither be regarded as a means of curing cancer, nor of prolonging the existence of persons affected with the disease." This melancholy conclusion should surely excite great caution in the use of the scalpel in every kind of morbid growth depending upon impaired health.

The conclusion which may be drawn from this very cursory view of the subject, may be summed up in few words:—

The extirpation of morbid growths may be said to be *indicated*, (their position being convenient for operation,)—1. Wherever the disease is clearly the result of local or mechanical irritation from some external source. 2. Whenever the tumour is neither painful, tender, nor progressive, the health being good. 3. Whenever it can be fairly demonstrated that the pain or irritation of the tumour being the primary and sole cause of disturbed health, its removal will be the least of two evils. 4. A tumour in the mamma, originally depending on disordered health, may, *after the health is restored*, become painful from the pressure of the dress, and thus the absorbent glands may be excited and the uterine functions disturbed. Excision may be justifiable in such a case; but the proper time must be chosen, and great attention should be paid to the health subsequently,

The extirpation of morbid growths may be said to be *contra-indicated*,—1. When failing health precedes or accompanies the appearance of local disease. 2. when the disease is advancing, the tumour sensibly growing, no local or mechanical cause of irritation being apparent. In this case it is right to assume the existence of latent constitutional disease, and to treat the case medically rather than surgically. 3. When there is a plurality of tumours. 4. When the disease reappears, whether soon or late after an operation for its removal.

The reader will observe that these rules contain little reference to the condition of the absorbent glands connected with the tumour, although surgical writers of the highest eminence have generally pointed out this circumstance as the one grand distinction which indicates or interdicts excision. Swollen axillary glands have always been held to be a strong objection to the removal of a tumour in the breast; and on the other hand, a healthy condition of these glands, has been admitted as a proof that the system is not contaminated, and that therefore the disease may be extirpated by the knife. Against this doctrine, (which appears to have been adopted by surgeon after surgeon from preceding writers without much reflection,) I must enter my most earnest protest. Nothing can be more fallacious in theory or unhappy in its practical results. Nothing is more common than the enlargement of the axillary glands from inflammation of the fingers, as in whitlow, or the introduction of any irritating matter or animal poison into the fingers. Yet, who infers from this circumstance, that these glands are the seat of incurable disease? They become irritated and swollen: but the irritation and swelling subsides spontaneously as soon as the exciting

cause is removed. On the other hand, malignant disease may pervade the whole system, and become developed in the mamma or any other organ, and exist in the form of a tumour for months together, the health evidently giving way, while the absorbent glands remain unaffected. The conclusion is, that it is not always advantageous or safe to amputate when the absorbent glands are sound; nor, when they are swollen and tender and inflamed, do they present any absolute proof that the whole system is contaminated. In those cases *where the question of excision can be entertained at all*, it is impossible to tell whether this secondary affection of the absorbent system be merely the effect of irritation, or an actual extension or translation of malignant diseases. How, then, can any thinking man regard it as an important indication for or against an operation?

Happily, hospital surgeons are becoming at length practically alive to the fallacy of this distinction; and it is one of the most pleasing features of the improved condition of modern surgery, that the treatment of morbid growths by extirpation, is now the *exception*, and not, as formerly, the *rule*.

The medical treatment of morbid growths, and the efficacy of alteratives in arresting their advance or destroying them altogether in cases unfitted for operation, will form the subject of a future paper.

Dec. 12, 1848.

CLINICAL ILLUSTRATIONS.

CANCER AND FIBROUS TUMOUR OF THE UTERUS: CASE AND REMARKS.

By EDWARD BALLARD, M.D., Leamington,

Late Senior Physician to the St. Pancras Royal General Dispensary, and Medical Tutor in University College, London.

Having been induced to offer as the first of my clinical illustrations a case of an unusual form of uterine disease, it may be as well for the present to confine my observations to such affections of the womb and its appendages as have come under my notice and treatment in the course of my Dispensary practice; in doing so it shall be my endeavour to select from among the unpublished cases which I have collected, those which on the one hand I have had the opportunity of recording with the greatest exactitude, or on the other which appear to illustrate important facts in pathology or practice. Nor shall I consider any apology needed on account of the details which I may think it desirable to enter into, believing as I do that there is no fact which well observed may not be without its value, and that if from circumstances it is not appreciated fully by myself, it may be of such a nature as to fill up some important hiatus in the reasonings of others.

CASE.

Injury to the Trunk; Menorrhagia; Abdominal Tumour; Vaginal Discharges; Involuntary flow of Urine; Death.—Post-mortem examination:—Fibrous Tumour; Scirrhus; Encephaloid and Fungus Hematodes of Uterus; Ovarian Tumour, &c.

This case was seen during life by my friend and colleague Dr. A. P. Stewart, who, after death gave me the opportunity of making an examination of the body. The following history I draw up from information derived from the patient's sister and a woman in whose house she resided, and it was kindly corrected by Dr. Stewart from what he recollected of the symptoms.

M. A. L., aged 42, a native of Norfolk, but having resided ever since she was twenty years of age in London, where she has lived upon the town during all that period as a common prostitute. The court in which she lived was one of the closest and most unhealthy in St. Pancras parish, and inhabited almost entirely by the class of persons to which she herself belonged. She was the eldest of eleven, and lost two brothers of consumption, one at the age of 19, the other at that of 23 years. She became a patient at the St. Pancras Dispensary, under the care of Dr. Stewart, very shortly before her death.

Although an inveterate spirit drinker, she had always had sufficient wholesome nourishment, and up to nine years ago is said to have enjoyed a good state of health. She had one child shortly after she came to London. About nine years ago a cab knocked her down in the New Road, and the wheel passed over her body. She seems to have considered herself at this time in the family way, but upon this there prevails some uncertainty. From this injury she used to date all her ailments, although it appears probable that previously she had been subject to occasional flatulent pains and swelling of the belly, which eructation always relieved. However, from the time of being run over, she was subject to menorrhagia, often of a month or six weeks duration, blood coming from her in clots. For the last four or five years and more, especially for the last three, she had noticed the abdomen to be enlarging to a degree quite unusual to her, and this, too, principally at the lower part; and she complained from time to time of the food she took disagreeing with her; and two years ago she began, for the first time, to complain of twisting pains, "as if her intestines were being tied into knots." In the month of February last year, (this report was drawn up in September, 1846,) she began to complain in addition of darting pains at the bottom of the belly, and swelling of the legs, which induced her to place herself in the Middlesex Hospital, where she was told that there was "a tumour in the abdomen." Being of a very reserved and uncommunicative disposition, it is highly probable that the pains she suffered had lasted for a long time before she made any complaint of them to her neighbours, and then did so only when their severity extorted it. She never suffered from any remarkable vaginal discharge till twelve or eighteen months before her death. About a

week before last Christmas she became unable to hold her urine for the ordinary period, and only passed it in small quantities at a time. She also told her sister that "a substance had come from her like bone and flesh," but she was frightened very much at it, and had thrown it away without further examination, and at the same time she suffered pain around the umbilicus and at the bottom of her back. Four months ago the vaginal discharge became very abundant and offensive, and her strength was reduced, but not extremely so. From six to nine weeks before her death, a black substance was discharged by the vagina three or four inches in diameter, which, according to the testimony of some one who saw it, resembled very much the matter found in the uterus after death, since then she appeared to have lost all control over her bladder, the urine passing from it constantly and involuntarily. At Christmas, too, her complexion began to assume the cancerous tint, and she began to lose her flesh. About a month or three weeks before her death there appeared some œdema of the ankles, which slowly extended to the thigh. She did not take to her bed, however, till three days before she died, during which time she lost her appetite, and passed her stools involuntarily. For the last nine days the odour of the discharges from the vagina was exceedingly offensive. She used to complain to Dr. Stewart very much of pain in the scapulæ. She never was sick or vomited, and her bowels were regular throughout. During the last three days that she was in bed she drank excessively of spirits and laudanum. She died on September 5th, 1846.

Examination of the Body fifty-nine hours after Death.—General, but not extreme, emaciation. Below the umbilicus there appeared a somewhat conical projection, occasioned by a tumour in the abdomen, which became much more obvious on handling it, and was manifestly of irregular outline; it was felt to extend upwards as high as the umbilicus, and laterally to within three fingers' breadth of the iliac spines, being most prominent in the middle line, and receding towards the sides, approaching the right, nearer than the left, ilium. The irregularity of outline was most remarkable on the right side and upper part, where it felt tuberos. It was moveable to a small extent; percussion over it elicited a dull note, becoming, however, rather less so towards the sides. Resonance pretty natural over the upper half of the abdomen. On laying open the abdomen by a vertical incision, the tumour was displayed, occupying the space between the pubes and the umbilicus, and descending into the pelvis, having on its right side the enlarged and diseased ovary, and being covered by the omentum which was adherent to the surface of the latter. The tumour did not adhere at all to the abdominal parietes. It consisted of the enlarged and diseased uterus, to which the left Fallopian tube was adherent along its left border, as also was the left ovary. The uterus, when removed, measured ten inches in length, and six inches in width, at the widest part. Its surface was even and smooth anteriorly, but presented tuberiform elevations at, the fundus, and posteriorly; two, hard and bony, imbedded in the tissue, projected at the top. They were about three inches in diameter,

and there were smaller tumours posteriorly, of about the size of a marble or walnut. The cervix uteri had completely disappeared, and the os was dilated to the extent of about two inches in diameter, its margin being thin, flabby, and congested, and it displayed within the uterus a dark-brown mass. On laying open the cavity of the uterus by a vertical incision on its anterior surface, it was found to contain a mass of fungus hæmatodes, which was not adherent anteriorly to the wall of the organ, but posteriorly and laterally was connected with irregular projections, of various sizes into the cavity, of cerebriform cancer. The mass of fungus hæmatodes was of a very dark reddish-brown colour, breaking down under the finger, but still presenting an amount of cohesion, which was greatest as it approximated to the cerebriform masses. In parts it broke down on pressure, into a dirty grumous liquid. It appeared to be in masses, which were connected to one another by films and thin cellular bands, pretty easily broken down, and these masses, when cut into, were seen to be rather granular on the section. The cancerous masses projecting into the cavity, when cut into, were found to be soft, traversed by numerous bands, and to present much the appearance of the surface of an infant's brain. In no part did this matter reach the outer surface of the organ. Some few flaky little pieces of bone were picked out of the hæmorrhagic mass near its attached portion. The tumours which projected externally were of two kinds; some of the smaller exhibited, on section, the aspect of scirrhus cancer, and exuded a cancerous juice on being scraped; others presented a structure similar to that of the two large tumours of the fundus. The latter were united by what appeared to be scirrhus texture. The largest was about the size of a duck's egg, oval in form, and consisted of a mass of fleshy-looking matter, fasciculated like muscular tissue, and pale, as if rendered so by a short maceration in water. This matter was enclosed in a flexible fibrous cyst, containing patches of calcareous matter. At one end of it was a small entirely calcareous cyst, of about a line, or sometimes more, in thickness, enclosing a similarly fibrous matter, but dense, and less like muscle, of a pale yellowish tinge, and drier than the former; it was evidently of longer standing than the greater part of the tumour. The other tumour which lay beside it was of a rounded form, and appeared to consist of several, aggregated and united, the walls of all being very dense and calcareous, and the enclosed fibrous or fleshy-looking matter varying from a pale red to a yellowish colour, and being denser, and of a drier texture than that before described. A smaller tumour appeared in a transition state; its cyst was partly osseous and partly flexible, the enclosed matter being denser and yellower near the former, and redder and more flesh-like near the latter, portion. None of these tumours reached the peritoneal surface of the womb, and although causing considerable projection, they were covered by a layer of hypertrophied uterine tissue. The general tissue of the uterus was hypertrophied, even where not diseased; the thickness of the anterior wall near the fundus was nearly an inch, and it thinned off gradually towards the dilated os.

The right ovary was converted into several masses similar to the fibrous tumour of the uterus, each more or less completely enclosed in an osseous cyst, the side of each tumour most ossified being denser also, and yellowish in colour. The kidneys were rather smaller than natural, very flabby and watery, very pale, and the cortical portion much diminished in width. There was nothing deserving record amiss with the other abdominal or thoracic organs. The cancerous tissue was submitted to microscopic examination. The brown hæmorrhagic matter in the cavities presented long and short caudate and spindle-shaped cells, as well as others which were round, compound, and nucleated—granules and blood-corpuscles in various conditions. The blood corpuscles and caudate spindle-shaped cells were not seen in the encephaloid matter. They were seen, however, in the fluid scraped from the scirrhus, along with crystalline matters and fibres.

REMARKS.

Pathology.—1. The limitation of the disease to the womb, although it there produced the most tremendous ravages, is a fact generally observed in cancer of this organ. If we may rely on the small number examined by M. Ferrus, a little more than a fifth alone have presented, in addition, a secondary cancerous complication. My own experience leads me to coincide in this respect with the general statement. I have, however, in one case met with uterine cancer occurring secondarily to cancer of the mamma, a thing so unusual that their union in the same person is generally denied. 2. The part of the organ affected was remarkable. The cervix, as every one's experience can testify, is the most common seat of cancer of the womb; at any rate, if the body be diseased, it becomes so by the spreading of the adventitious growth from the former part. Here, however, the cervix was free, and the body was the only part which suffered. The posterior wall, too, was alone affected. Persons accustomed to dissect cancerous wombs are aware of this disposition of the posterior part of the body to take precedence of the anterior in presenting the morbid change, and the same tendency is noticed in the posterior lip, where the cervix is the part attached. The outer layer of the uterine tissue again was free from cancerous deposit, as if the disease had commenced on the inner surface, perhaps, in the submucous tissue, or in that part of the wall which was nearest to it. The freedom of the anterior wall was the more remarkable, that there was no trace of disease on its inner surface to indicate that it had lain so long in contact with the fungous mass which projected from the posterior. 3. The unusual combination of scirrhus with encephaloid, the latter the more unusual of the two varieties which affect the womb, the occurrence of colloid in it at any time being exceedingly doubtful. The fungoid and hæmorrhagic growth of it from the interior of the body, so as to form a soft tumour, distending its

cavity, is very uncommon; it was the "fungus hæmatodes" of Hey and others, and nothing more than an accidental condition of the encephaloid matter. 4. The co-existence of the fibrous tumours with cancer of the uterus deserves a few observations. It is common to find them together, and it would be a matter of much interest to determine in what relation they stand to one another. In the present instance everything connected with their anatomical peculiarities, and with the history of the patient's ailments, would lead to the belief that they had preceded the development of the cancer; they presented distinctly two periods of formation, the more recent, perhaps, was simultaneous with that of the cancer. It happens about as often that the fibrous growth succeeds the cancerous, and this not of the uterus or ovaries alone; but judging by my own experience, of the pylorus, or other abdominal or more distant organs, I have found it occur more rarely as a solitary affection, than in conjunction with cancer or other tumours in important organs of the body. I would not, however, be understood as believing that the fibrous tumour has any generic similarity to the cancerous, or that it exhibits any special disposition to assume a cancerous character, as an after-phase of its development; on the contrary, it has its own modes of morbid progress, one of which is illustrated in the case under consideration. Still the coincidence of the two kinds of growth is highly interesting, especially when we keep in mind that the only element necessary to convert a fibrous, into a scirrhus, tumour, is the interstitial deposition of cancer-cells. I make no allusion to the arrangement of the fibrous element, which, on competent authority, is essentially different in the two cases, but merely to the presence of certain microscopic elements; because, as I remarked before, fibrous tumour and cancer must by no means be confounded. 5. Hypertrophy of the uterine tissues when free from morbid growths, was a remarkable feature in the condition of the organ, and had occurred to an extent beyond anything I had formerly witnessed in cancer of the womb. Dr. Walshe, in speaking of this complication, says he has known the uninfiltreated portion of the uterus acquire three times its natural dimensions. It is in the soft, rather than in the scirrhus, cancer of the womb, that this hypertrophy prevails. 6. The condition of the cervix and os uteri deserves remark; the latter was absolutely lost by atrophy and distension, while the os was singularly dilated. I have notes of another case of somewhat similar alteration of the cervix, where the womb was the seat of an enormous fibrous tumour. At a future period I shall probably relate it. In both instances the cause was probably the same as that which determines similar changes in advanced pregnancy. 7. Although I purposely omitted it from the report as of accidental origin, I would here desire to allude to a phenomenon presented by the uterus

when removed from the pelvis,—namely, that as it lay upon the table, *percussion over the central part of the body elicited a distinct resonance*. There was no mistake about this, as the experiment was repeated, and Dr. Stewart heard it as well as myself. I mention it here partly because it gives me an opportunity of alluding to a similar resonance which I have observed over the right front of the chest in a man who had died with pneumonia of the right lung. In this case the resonance was noted as “almost tympanitic.” This, too, was confirmed by the testimony of a medical friend who assisted me in the examination, and was surprised at seeing a consolidated lung enclosed in a resonant chest. Both these occurrences must be attributed, not to any peculiar condition of the uterus or chest, but to some peculiarity in the mode or direction of the stroke, which the solid tissue conducted to the vibrating table on which they severally rested.

Physical Signs.—A few observations may not be out of place in relation to the physical evidence of the uterine disease as presented by external examination after death. In the first place there was not merely fulness, but a positive projection, obvious to the eye, at the lower part of the abdomen, which immediately attracted the attention on uncovering the latter. This was due to the tuberiform elevations resulting from the fibrous tumours in the substance of the womb. I cannot tell whether this sign existed during life, but at all events the tumours of the uterus must have been palpable to the hand. The fact that such can be felt, teaches this lesson, that we are not immediately to conclude on this account that they are *subperitoneal*. The determination of this point is of practical importance, since uterine hæmorrhage is far more rarely connected with them in this situation than when placed near the inner surface; still should the error occur, it would be on the right side, as it would lead to the further investigation. The general enlargement of the womb felt by the hand could only have been mistaken for that arising from pregnancy. A vaginal examination, however, during life, had the enlargement been detected at that time, would readily have distinguished between this and hypertrophy of the walls. In the former the cervix would not have been so completely obliterated at the period supposed to be arrived at, and the enlargement of the organ would have been felt more towards its anterior than towards its posterior walls. The partial mobility of the enlarged organs was indicative of what was observed after death,—namely, the absence of important adhesions, or of the extension of cancerous degeneration into the broad ligaments and neighbouring organs. In all this, however, there was no evidence of cancer of the womb. What, however, would have been ascertained, had vaginal examination been practised during life? A stretched, thinned, and, so far as its

natural form was concerned, an obliterated cervix; the os uteri most unusually opened and extended in its diameter, and occupied by a fungous growth, which would easily have been recognized as extending, at any rate, some way into the general cavity. This state of things only occurs, so far as I am aware, when the uterus has been distended by growth or deposit into its cavity, or by very unusual degeneration and tumour in its walls. The two cases might have been distinguished by ascertaining the size, duration, and contents of the uterine cavity, by means of the finger, speculum, or uterine sound. In the present instance I think there should have been no mistake in the diagnosis, had all the available means been adopted for ascertaining the physical condition of the diseased organ.

Symptoms.—In every chronic affection the symptoms of the disease are divisible into certain periods, which the practitioner should ever keep in mind. Before a chronic local disease can be said to have plainly manifested itself, there is mostly discernible a period of greater or less duration in which the patient is “ailing;” the general health is defective, and there is some degree of general debility and slightly disordered function, mostly exhibiting itself in the digestive and circulating system, and in the condition of the urine; these, from their very gradual accession, are commonly overlooked or attributed to occasional or incidental coincidence. It may be well if the acuteness of the physician prevents his being so readily led astray, and if he be impressed with the fact that so intimately is every function of the body connected with every other, that a disturbance in one, however trifling in amount, yet if prolonged in duration, ensures most certainly a derangement of the rest; it may be well, moreover, for the patient if the original source of his disorder be timely discovered, and be such as medical art can reach. The next stage is that of formation of the local disease. This may date its commencement from some accidental occurrence, some trifling local injury, or the latter may, by drawing attention to the seat of disease, merely unveil what had perhaps for months or years been slowly, insidiously, and painlessly, yet irremediably, not only disturbing function, but undermining structure. The symptoms of this period pass gradually, or perhaps after a prolonged latency, with the most fatal and uncontrollable rapidity, into those of the confirmed disease, in which for the most part the sensations of the patient direct the practitioner pretty surely to its seat, and in which far more frequently than at an earlier period of its development the assistance of his art is commonly sought. The last stage is that which immediately precedes dissolution; the symptoms of the local affection may be obvious and urgent, but they are very often marked by those which arise from excessive constitutional prostration, or from accidents—the result of the original disease, or

of the depression of the powers of life. The true physician's art is in this, and perhaps even in the preceding period, limited to the melancholy, but not the less important duty of soothing by his presence, his attention, and by the moral influence which he cannot fail to exercise, the mental disquietude of his patient, and, by gentle remedies and incessant watchfulness, of alleviating his bodily suffering, and rendering less troubled his journey to the grave.

In the present instance there is little record of the state of the patient's health previous to the development of the uterine disease, the only notice of ailment being, that she had probably suffered from the same abdominal flatulence and pain which used to trouble her more or less through the whole period of her illness. The first symptom of uterine disease was the occurrence of menorrhagia. Violent and repeated flooding, not to be accounted for by something in the state of the general or portal circulation, should always lead the practitioner to enquire into the structural condition of the uterus, and to institute a most careful investigation into the physical state of the organ. It is most likely that its first occurrence was determined not by the cancerous disease, for this was of more recent origin, but by the fibrous tumours in the uterine walls; and it is much more frequently when these approach the inner, nearer than the outer, surface of the organ, that they occasion hæmorrhage. I am not disposed to place any reliance on a "clotted" discharge as indicating uterine disease. Darting pain at the lower part of the belly, swelling of the legs, and vaginal discharge, would appear to have ushered in the more serious cancerous affection. The pain, however, was not of the all-absorbing character which is observable in the more ordinary forms of uterine cancer, being perhaps complained of less than any thing that the patient suffered, not even being such as to compel her to keep her bed; nor was it as in cancer originating in the cervix, described as darting through the pelvis. The character of the vaginal discharge when it first appeared could not be ascertained; but nine months before her death there passed from the vagina a substance described as similar to bone and flesh. A better similitude could not have been selected to represent the character of the fibrous tumours existing in the uterine wall, one of which had no doubt become enucleated in the progress of the disorganization. I would again impress on all who are called on to treat diseases of the womb, the importance of relying in no case on the statements of the patient herself as to the nature of the matters which pass from the vagina. They are as important as means of diagnosis, as the discharge from any mucous surface in the body, as much so as those of the lungs in pneumonia, or of the bowels in abdominal disease. The examination of this mass would of itself have afforded the most conclusive evidence, not only of

fibrous tumours existing in the uterine wall, but also of their situation with respect to the interior of the organ, while the calcareous degeneration it had undergone would have pointed it out as of no recent formation, and as the probable cause of the protracted menorrhagia. It was not until some months after this period that the vaginal discharge became offensive. It is not unlikely that the separation of the tumour gave room for the exuberant fungous growth which sprouted from the encephaloid mass into the cavity of the organ, just as in superficial cancer the removal of a restraint upon its surface is followed by a similar result. But I have not yet done with the instruction derivable from careful examination of vaginal discharges. We are informed that a few weeks before death a black substance passed from the vagina resembling the fungoid growth which filled the cavity of the womb—no doubt part of it. Had a portion been placed under the microscope, little doubt of its cancerous nature would have existed in the mind of the examiner. It is to be regretted that among practitioners in general this means of investigation is so little resorted to in the diagnosis of uterine disease. Applied to the urine, it has opened a field of the most valuable information, and advanced in an extraordinary degree our knowledge of renal disorders.

The discharge of this fungoid matter ushered in the latter symptoms of the complaint, which had reference, not to the uterus alone, but to adjoining organs. A difficulty in retaining her urine, which had annoyed the patient ever since the discharge of the fibrous mass, passed on into complete incontinence, partly due to paralysis, and partly the result of diminished capacity of the bladder from the bulk of the enlarged womb. She lost her appetite, and with it the remaining portion of her strength, and the sphincters of the anus ceased to perform their function. These are common occurrences during the last days of uterine disease.

Hospital Reports.

QUEEN'S HOSPITAL, BIRMINGHAM.

CLINICAL REPORTS OF SURGICAL CASES UNDER THE TREATMENT OF PROFESSOR SANDS COX, F.R.S., SENIOR SURGEON TO THE HOSPITAL.

Reported by Mr. PETER HINCKES BIRD, late Resident
Medical Officer.

CASE XVI.

FRACTURE OF BOTH BONES OF THE LEG.

John Jelf, aged 21, was admitted into the Queen's Hospital April 13th, 1847, under the care of Professor Cox. He is a labourer; temperate and healthy. He states that about a quarter of an hour previous to his admission into the Hospital, whilst lifting a heavy

weight, he fell down with his right leg bent beneath him, and that all motion in the limb was immediately lost.

The leg was considerably shortened, and the foot was turned inwards. On examination it was found that the tibia was fractured in two places, the higher fracture being at the middle, and the lower at the upper part of its lower third; a small piece of bone was also found broken off from the lower portion. The fibula was broken near its middle. There was slight swelling.

The leg to be placed on Sharpe's external splint, and fomented with warm water.

14th. The swelling is considerable, accompanied with ecchymosis and some pain. Bowels confined. Extr. Colocynth Comp., gr. x., hora somni sumenda.

17th. Bowels open; the pain and swelling are nearly gone. The limb to be put in splints. A long, straight, concave splint was placed on the posterior part of the limb, extending from the middle of the thigh to near the heel, and very carefully padded at the popliteal space and above the heel, so as to adapt it exactly to the size and shape of the calf; this was then fixed by a few turns of bandage at the ankle and above the knee, considerable extension being kept up. Two lateral splints were then applied, and confined by tapes. The limb now looks very compact and straight, and the patient says he feels great comfort and support.

20th. Doing well; the comminuted portion of the tibia can be readily felt, but the bones are in good apposition.

May 12th. The splints were removed this morning; the fractured parts are united, and appear pretty firm. Splints re-applied.

May 29th. The bones are firmly united; a starch bandage was applied, and on the following day the patient was discharged with a perfectly straight and sound limb.

CASE XVII.

OBLIQUE FRACTURE OF THE TIBIA.

John Oxford, aged 58, boatman, admitted into the Queen's Hospital March 20th, 1847, under the care of Professor Cox. He states that about half an hour previously he was jammed between two carts; the wheel of one went over his foot, and having hold of the other cart, his left leg got twisted, and he immediately lost the use of it.

On admission there was an oblique fracture of the tibia at its lower third; a sharp point of the upper fragment was nearly through the skin. The lateral splint was tried, but it was found that it was impossible to keep the parts in apposition, and the straight principle was resorted to. The heel was well raised, in order that the upper sharp point of bone might be brought in a level with the lower; the point did project a little, and a small pad was found necessary to make it lie in perfect contact. He was discharged on the 14th of May.

CASE XVIII.

OBLIQUE FRACTURE OF THE TIBIA.

Arthur Howse, aged 45, carman, admitted into the Queen's Hospital, on May 1st, 1847, under the care of Professor Cox.

He states that about five months previously he slipped off a step, fell down, and twisted his left leg, which bent under him; he felt the bone break, and

immediately lost the use of the limb. On admittance the left leg was found distorted; the tibia was very obliquely fractured downwards and forwards at the lower part of the middle third; there was also a wound over the seat of the fracture, through which the sharp point of the upper portion of the bone nearly protruded.

This case was treated exactly as the last, and he left the hospital on the 10th of July, quite well, with a straight and sound limb.

CASE XIX.

OBLIQUE FRACTURE OF THE TIBIA.

John Kerkoff, aged 65, tailor, was admitted into the Queen's Hospital June 13th, 1847, under the care of Professor Cox. He states that about an hour ago he slipped down stairs and struck his leg, which was doubled up under him; he immediately lost the use of it, and experienced great pain.

On examination it was found that the right tibia was fractured very obliquely downwards and forwards, about an inch and a half above its inferior extremity. The leg was put up on the straight principle, as in the preceding cases, and the bone was firmly united on July 3rd.

1. *Remarks upon Fractures of the Leg in general.*—Fracture of the bones of the leg is a very frequent accident, which is accounted for both on account of their situation, exposing them to injury, and the weight of the body telling directly upon them, by reason of their position; for when a person falls, the leg may be variously placed, and so enable a force to act upon it, which will have no effect upon the femur.

The bones of the leg are scantily protected by muscles, the anterior and inner surfaces of the tibia being only covered by integument, and this circumstance may account in some degree for the simple fracture, but more especially for the compound fracture, being more frequent in the leg than in the thigh; and compound fractures of the leg would occur oftener than they do, but the force that causes them generally acts in a direction from the integument.

The reason why the tibia and fibula, unlike the bones of the forearm, are more frequently broken than either bone singly, is, that a force sufficient to fracture the tibia is for the most part generally sufficient to extend to the fibula afterwards, and break it.

The situation in which the bones of the leg are broken depends on the kind of force applied,—namely, the direct and the indirect. The head and the lower extremity of the tibia can never be under the influence of indirect violence, but must have a force directly applied, in order to fracture them, whilst the middle of the bone can be broken by both forces.

The above cases occurred from forces indirect; for example, take the case of Jelf. Falling with his leg obliquely under him, the lower end of the tibia was fixed by means of the foot upon the ground, and the upper end to the femur,—two points capable of resisting force, owing to the weight of the body, which then extended to the shaft of the bone and broke it, without the aid of any direct violence.

In Oxford's case some direct violence might have been added, but I think the twist was the main, if not the only cause of fracture, there being no bruising of the part.

In the case of an old woman who was admitted

with fracture of the head of the tibia, it was caused by direct violence.

2. *A few Observations on Fractures of both Bones of the Leg.*—The bones of the leg are sometimes broken opposite each other, but more frequently the tibia is broken at one point and the fibula at another: and this depends upon the kind of force that produces the fracture, for when a direct force acts, the former takes place, and from an indirect one, the latter. This is easily understood, for when we consider the difference in size and shape of the two bones, it cannot be inferred that both can offer the same resistance, and the consequence is, that when an indirect force acts, it first fractures the tibia, perhaps, at its centre; it now comes to the fibula, and in consequence of the tibia being broken, the force acts in a different line,—namely, more obliquely than it did on the tibia, so that the difference in *shape and strength of the bone, and its changed point of resistance together*, cause the fibula to break at a remote point from that at which the tibia yields.

In most cases I have found the fibula broken at a higher point than the tibia, when the accident had occurred from an indirect force, and the tibia is very commonly broken near its centre, and the fibula an inch or two higher up.

The fracture is generally oblique through the tibia, the cause of which depends upon its shape, which makes the bone to resist differently in various parts, and so alter the line of direction of the force. The direction of the fracture is generally downwards, inwards and forwards liable to modifications. The tibia may sometimes be comminuted, but this generally results from direct violence, and the brittleness of the shaft is favourable to its production. The fibula is generally broken transversely, but sometimes obliquely.

Fractures of both bones of the leg are easily detected, but not so when only one bone is fractured, the symptoms being far less prominent, for the displacement and retraction which takes place in the former cases, may be entirely absent in the latter.

The muscles of the leg offer greater resistance in reduction of the bones, than in any other kind of fracture, by reason of so many powerful muscles passing from one part of the leg to another, and acting upon two portions of bone, thereby favouring retraction, and creating great difficulty in keeping the fractured ends in apposition.

3. *Remarks upon the Treatment and Description of the various Modes adopted in Fracture of both Bones of the Leg, and why the Straight Principle was preferred in the above Cases.*—Fractures of the leg are, perhaps, more difficult to treat than any other kind of fracture, for the muscles that cause the displacement of the bones are powerful, and are so situated, that they frequently draw the ends of the bone out of apposition, and require great force to overcome them. The first thing to be done is to place the limb in the most favourable form to relax the muscles, and to do this we must consider the position of those muscles that are most disposed to contract, and ascertain the precise point from which they act.

The gastrocnemius and soleus are the chief muscles in causing displacement of the fractured portions, the deeper muscles having very little influence on account of their peculiar mode of origin, and the direction of their fibres, which do not allow them to shorten much.

The position most favourable for the relaxation of the muscles is obtained by placing the knee in a state of flexion, so as to make the tibia form a right angle with the femur, and the foot a right angle with the leg. This is done either by placing the patient on his side, or on his back, and in the latter case, using the double-incline plane.

Since the days of Pott, fractures of the leg may be said to be treated by position only; he made position his grand object, always taking care to place the limb, so that all the muscles might be relaxed as much as possible, by which little or no mechanical force is wanted afterwards to keep the fractured portions of bone in apposition. The limb is placed on its outer side, and the hip and knee-joints flexed, by which the most powerful muscles are relaxed, and tendency to spasm prevented. One straight splint is placed on the outer side of the leg, extending from above the knee to below the ankle, and another splint of the same length is placed on the inner side, care being taken to pad each properly. This is undoubtedly a good method of treatment, and the simplicity of its application, and its requiring no apparatus but what can, under any circumstances, be always obtained, are certainly great recommendations; but I shall presently point out some objections to this principle of treatment, and the great advantages of the straight one. The objections to the former are, the tediousness and inconvenience of keeping the patient confined a long time on his side. I have heard many patients complain, especially those of short stature, of great inconvenience from this position, and the consequence is, they endeavour to turn on their backs, which cannot be done without moving the leg from its proper position, the level of the knee is altered, and therefore it does not lie in proper relation with the foot, for the latter will remain flat on its outer side, while the upper portion of the bone is taken with the knee. It is often advisable, however, to adopt this treatment at first, and alter it afterwards; for the limb may be so much bruised or swollen, or the spasm may be so great in the muscles, that it is often quite impossible, and would be even cruel, to use any means that confine the limb, or place it in any position that puts the muscles on the stretch. When the swelling has subsided, and the soft parts recovered themselves, the straight position may be chosen with advantage.

The splints that are best adapted for treating fractures of the leg in this manner, are those of Mr. Sharp, which consist of two portions of wood or iron hollowed out, and made of the width of the leg, taking also the shape of the limb. Each splint is hollowed out for the malleolus, and they may be kept in position by three or four straps, or by passing strips of bandages round them.

Another objection to this principle of treatment, besides that alluded to, of confining the patient so long on his side, is, that when there is any disposition for the one portion to ride upon the other, it has no mechanical advantage over the ends of the bone, all it can do is, to steady the two ends of bone generally, and keep the joints that are connected with them at rest.

I shall now mention the modes of treatment which require the limb to be placed on its posterior surface; they answer admirably, and are without the inconvenience of laying the patient on his side.

The apparatus (the most simple in its application,

and generally the most beneficial in its results,) is that known by the name of the "junks." It consists of two rollers of wood or straw, long enough to extend below the ankle and above the knee. They are included in a piece of linen, by being rolled within it, the leg resting on its central portion; each roller is then rolled until it comes in contact with the leg, one being on the outside, and the other on the inside of the limb; they are fixed by a few turns of bandage at the ankle, and just below the knee, and the posterior part of the leg is left lying upon a well-padded pillow.

This method, with an additional splint, has been followed at the Queen's Hospital during the last year with very satisfactory results. Instead of rollers of straw or wood, two of Sharp's splints are used, one being placed on each side of the leg, and the additional one—a long concave splint, is placed on the posterior part of the limb, reaching from the middle of the thigh to near the heel.

The following is the method of applying this apparatus:—The surgeon takes charge of the limb, and whatever reduction of the fracture may be necessary, is first to be made. The leg is then raised from the bed by grasping the knee with one hand, and the instep with the other; when raised to a sufficient height, an assistant places the long concave splint, well padded, beneath the limb, and it is then fixed by a turn of bandage above the knee, and by another at the ankle; Sharp's external splint, with a foot-piece, is now to be placed on the outer side of the leg, and there fixed by a bandage, after which an internal splint is placed on the inner side, and fastened by tapes. The advantages of this method of treatment are the following:—It fixes the leg firmly, for, if properly applied, the pressure will tell all along the limb. Any degree of pressure may be made by tightening the tapes.

The limb can always be examined without disturbing the parts, for when the side splints are removed, the *foundation* one remains.

The anterior part of the leg is always exposed and open for inspection. The finger can be passed down the anterior part of the tibia, and any irregularity can easily be detected; lotions can be easily applied, and if displacement be dependant on position only, and not upon spasm, the heel can be raised or depressed, according to circumstances, by appropriate padding.

This has also a great advantage over the common "junks," as it remedies the only possible evil to which they are liable, namely, the sinking of one or other portion of the bone posteriorly, owing to the pillow on which the leg rests yielding; now, this is all guarded against, for if the posterior splint be firmly padded, it cannot give way.

The principle on which this apparatus acts is merely to steady the limb generally, and from its position the portions of bone are kept in a right line. The apposition of the ends of the bone is not at all interfered with by the limb being placed on the posterior surface, and gives the patient the additional advantage of lying on his back, which is so much more comfortable, when the same position has to be continued for some time.

The above cases, which were all awkward fractures, speak favourably of this method of treatment, and I have come to the conclusion that it is the best method of treating fractures of both bones of the leg. The whole apparatus when applied looks very compact and

neat, and the patients express themselves as feeling great comfort and support from it. It is also particularly applicable when the patient is restless; it completely guards against any accident. The posterior splint fixes the limb so firmly, that when well bandaged, the patient may throw his leg in almost any direction without the fear of displacing the portions of bone. There is another apparatus which may be employed with great advantage in some cases, where the fracture is very oblique, it is a modification of M'Intyre's splint by Mr. Liston. This has no advantage over the previous method of treatment, except that from the lower part of the leg-piece being absent behind, the heel can be very easily raised or depressed at any level.

Although I have recommended the straight principle very strongly, I do not mean to say that it will succeed in all kinds of fractures, and the surgeon must be guided by the circumstances of the case, and adopt that apparatus which will best fulfil the indication pointed out by the state of the limb, and the kind of fracture.

PROVINCIAL *Medical & Surgical Journal.*

WEDNESDAY, MAY 2, 1849.

It is sincerely to be regretted that a want of integrity should so frequently be observed in connection with the purchase and transfer of medical practices. There can be no valid objection to professional negotiations for mutual benefit, so long as the conduct of the parties is regulated by honourable principles, but we fear that the fair and legitimate intention of the vendee is, in many cases, frustrated by the wilful misrepresentations of the vendor. The temptations to deviate from the path of honesty are, in some instances, very strong, and the facilities for fraud are so great as to render the utmost wariness necessary for the prevention of imposture. The members of the medical profession are, unfortunately, often placed in circumstances of pecuniary difficulty, and are urged by privation and distress to employ disreputable means for the temporary supply of that maintenance which the exercise of their calling has failed to yield. Under the depressing influence of poverty the spirit loses some portion of that moral sensitiveness by which it was guided in former days,—when the sky of life was comparatively free from clouds, and recourse is had to a system of trickery by which a brief advantage may be gained.

The plan whereby this end is oftentimes accomplished, is the following:—Books are

prepared containing a long catalogue of patients, who either have no real existence, or, if they have, are not in a condition to pay the fees that are fictitiously entered to their account. These books are produced to a young stranger, who is anxious at once to enter into practice. He reads over the list, is captivated by the address and apparent ingenuousness of the deceiver,—feels a glow of excited hope as he calculates the aggregate of figures,—hastily closes with his new acquaintance,—pays the money that is demanded,—and subsequently discovers, by gradual but unquestionable evidence, that he has been *completely duped*. He perceives when it is too late, the folly of his precipitate decision, and vainly reflects that careful enquiry from disinterested parties, rigid scrutiny of character, and the aid of judgments more matured than his, would have prevented both his disappointment and his loss.

Human nature is too subtle to be readily apprehended,—too complex in its machinery to be easily understood. They who fancy themselves secure, because the surface of the lake looks smooth, will ere long find that the sharpest rocks may lie concealed beneath the most tranquil waters.

We would earnestly caution our brethren, and especially our *younger* brethren, never to be beguiled into *hasty* arrangements for the purchase of a practice, and not under any circumstances to place implicit reliance upon unsupported statements made by *interested* persons. If you hear of a favourable partnership or introduction, go and ascertain by actual observation how far the facts correspond with the description, and wait for the result of that testimony before you finally decide. Do not be hurried by the assurance which is frequently given, that other people are in treaty, and that unless you immediately acquiesce your chance will be entirely gone. Such urgency may occasionally be well founded, but in the great majority of cases you are justified in *suspecting* the truthfulness of those who seek to compel you to take an important step without allowing time for due consideration.

On the other hand, disappointments may arise from too much self confidence on the part of the vendee. He finds a *bona fide* practice established and maintained for many years, and he imagines that the payment of a certain sum of money is all that is required to place him in the favourable position of the original possessor. A little careful thought will shew the fallacy of

these sanguine anticipations. It is almost impossible that the entire interest of a medical practice can be speedily conveyed to a second person, particularly if he be younger and less experienced than his predecessor; and it generally happens, that he who buys is younger and less experienced than he who sells. It is also generally true that, where there are several medical men of long standing in the same town, the confidence of many patients is so *prospectively* engaged, that when their regular attendant has retired they will consult one of the former residents rather than a new-comer, with whose character they may be unacquainted. A great amount of vexation and loss might be prevented if those who intend to purchase practices would first learn, by *personal attendance*, what proportion of patients may fairly be regarded as secured. We think that an *honest* man would willingly allow every facility in his power to enable either a partner or successor accurately to estimate the nature of the circumstances; and we should always feel distrustful when we detected a tendency to introduce, rather than to remove, obstacles that might prevent the opportunity of thorough investigation.

Our remarks are not speculative but strictly practical, and are founded upon the bitter experience of many a young but too confiding expectant of professional success. There are unprincipled men in every department of science, and our own department is far from being exempt. The imperfections of our nature are variously exhibited, and multiplied are the instances in which genuine and high-toned principle is manifestly absent, although circumstances may not lead to the development of the whole extent of evil to which the inherent depravity is adequate. We should all strive to counteract the *primary* indications of every thing that is sordid and ungenerous, and to cultivate, with constant assiduity, those exalted sentiments which confer honour and dignity on man; and, in proportion as the *individual* members of our profession shall regulate their conduct to each other and to the world, by high and noble feelings, in that proportion will our *aggregate fraternity* be entitled to admiration and respect. We must not look to Parliamentary enactments,—to National Institutes,—to nominal distinctions, as the foundation of our stability and welfare, but to the firm basis of personal benevolence and integrity, upon which alone can be established a permanent superstructure of courtesy and truth.

Proceedings of Societies.

BATH AND BRISTOL BRANCH OF THE PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION.

A Quarterly Meeting of the Bath and Bristol Branch of the Provincial Medical and Surgical Association was held at the Medical Library, Orchard Street, Bristol, March 22nd, 1849, Farnham Flower, Esq., President, in the chair.

There were present—Drs. Lindoe and Davies, Messrs. Norman, J. Soden, Waldron, J. King, Brace, Bartrum, of Bath; Parsons, of Beckington; Cockey, of Froome; Crang, of Timsbury; Drs. Symonds, Green, Trotman, Kay, and Budd, Messrs. Neild, Lancaster, Ogilvie, Mayor, Surrage, Prichard, Godfrey, Estlin, Swayne, Jos. Swayne, Clarke, and Colthurst, of Bristol. Visitors: Dr. Boyd, Messrs. Harrison, W. Smith, and Gillow.

The minutes of the last meeting were read and passed. Dr. Symonds read an elegant and elaborate eulogy on the late Dr. Prichard, one of our venerated presidents, upholding the propriety of doing so, not only by reference to the custom of the ancients, but also by the kindly effect it produced on our better feelings. A few anecdotes of Dr. Prichard's early life shewed him to be of a literary and studious caste. He pursued his medical studies at Edinburgh, where he graduated in 1808, choosing for the subject of his thesis "The History of the Various Races of Man." This, it is demonstrated, formed the foundation of his work on æthnology, the first rudiments of which he published in 1813, and which Dr. S. characterized as the great work of his life—the work by which he would go down to posterity, whilst he pointed out the various modifications and gradations through which it passed, until it arrived at maturity in 1846. Dr. S. also enumerated various literary and scientific works which he published on collateral subjects, especially noticing the one on "Ægyptian Mythology," in 1819.

Although thus occupied, Dr. Prichard was not inattentive to his professional studies, as evinced in that splendid and truly practical work "On Nervous Diseases;" and in a paper published in the *Medical Gazette*, Jan., 1831, on "Incisions along the Sagittal Suture in Diseases of the Brain." A paper on the same subject being read by him before the British Association at their meeting in Bristol, in which the incision was shown to be more beneficial in chronic than in acute diseases. Dr. Symonds noted his appointment as Physician to St. Peter's Hospital, in 1816, to the Bristol Infirmary, and the great interest he took and the share he had in forming the Bristol Philosophical Institution, and laid great emphasis on the universal esteem in which he was held by his medical brethren for his urbanity and integrity; the general regret at his retirement from Bristol being in some degree counterbalanced by the advantages he obtained from his appointment as one of the Metropolitan Commissioners in Lunacy.

Dr. Symonds enumerated his various honors, specially describing in very forcible language, the meeting in the library at Oxford, when the honorary title of M.D. was conferred on him by that University.

Dr. S. then concluded his address by an able analysis of Dr. Prichard's mental powers.

Messrs. Norman and Colthurst hoped that Dr. Symonds would kindly publish the paper then read.

Mr. King trusted that it would be in the volume of *Transactions*, and not in the *Journal*.

Dr. Symonds stated that he proposed publishing it, but had not as yet determined on the form of doing so.

Mr. Parsons, of Beckington, read a paper "On Infantile Diabetes in a Child weaned at two months, and accustomed to be quieted by the use of a sugar teat, in which way he consumed from three quarters to a pound of sugar daily." Dr. Kay considered the case interesting as a specimen of diabetes artificially induced in the human subject; and Dr. Budd referred to the experiment of Dr. Percy, of Birmingham, who fed a dog on sugar until diabetes was produced.

Mr. Bartrum and Dr. Davies mentioned some remarks published in the *Archives Générales*, on animals fed entirely on meat and yet secreting sugar in the urine.

Mr. Bartrum, of Bath, read a paper "On Pelvic Abscess, arising from Inflammation of the Peritoneum." He referred to two cases occurring whilst he was clinical clerk to Dr. Watson, at the Middlesex Hospital, as first exciting his attention. He then gave the details of several private cases of phlegmonous abscess in cellular membrane of the pelvis, and also noticed inflammation of the ovaries as sometimes the exciting cause.

Mr. Norman spoke of the frequency of abscess in the pelvis in the female, relieved variously by discharges from the vagina, rectum, &c., gradually or suddenly as may be; also abscesses by the side of the rectum in the male assuming the appearance of ordinary fistulæ.

Mr. Lancaster introduced a case of lumbar abscess, consequent upon parturition.

BIRMINGHAM PATHOLOGICAL SOCIETY.

January 4th, 1849.

FREDERICK RYLAND, Esq., in the Chair.

SUICIDAL WOUND OF THE LARYNX AND PHARYNX.

Mr. Pemberton gave the following history of this case:—

A. C—, aged 36, of the Jewish persuasion, was brought to the hospital at nine a.m., December 21, 1848, under Mr. Wood, having cut his throat with a razor an hour and a half previously. He was pale and cold; there was urgent dyspnoea; and he had a restless wandering appearance. The wound was five inches and a half long; the right extremity was distant an inch and three quarters, the left two inches and a half from the lobe of the corresponding ear; its direction corresponded to the direction of the thyro-hyoid space, dividing the structures intervening between the surface and the pharynx, which latter cavity was opened for two-thirds of its circumference. At every inspiratory effort the larynx uttered a loud stridulous noise, and at times its action was evidently spasmodic. There was a good deal of venous oozing, but no arterial jets; the carotids could be distinctly felt pulsating; above, the os hyoides could be well marked by the finger, deprived of all structures below by the effect of the incision. An attempt was made to pass an œsophagus tube into the stomach, but the most alarming symptoms of asphyxia were thereby induced.

Breathing became gradually more and more oppressed, and the patient died at twelve, four hours after the infliction of the wound.

Sectio cadaveris twenty-four hours p.m.—Frame compact and muscular; large adipose development; stature small; marked Jewish configuration. Upon external inspection the penis appeared bruised; the anterior surface of the scrotum appeared slightly ecchymosed. The wound had divided the epiglottis in half, the one portion attached by its membranous folds to the os hyoides remained at the back of the tongue, whilst the base lay close upon the rima glottidis, closing it with the exception of a slight interval between the cut surface and the laryngeal aspect of the arytenoid cartilages. The thyroid arteries and the external jugulars must have furnished the hæmorrhage, the main vessels being uninjured. The trachea, bronchi, and their subdivisions in the lungs, were plentifully filled with frothy blood; no blood had passed into the œsophagus, but the stomach contained a large mass of undigested food. The left lung was adherent by some slight pleuritic bands, otherwise it was healthy; no spots of pulmonary apoplexy were discovered. The cavities of the heart were generally distended with dark fluid blood, as were also the aorta and the great branches from the arch; this condition of fulness of the vessels was more especially marked on the right side of the organ. Head not examined. The remaining viscera did not present an exsanguined appearance.

Mr. Pemberton ascribed death in this case principally to a state of asphyxia, induced in part by the presence of so much blood in the trachea and bronchi, and partly by the base of the epiglottis falling like a valve upon the glottis, so as partially to close it, being deprived of the support afforded by its attachment to the tongue by its separation from the main body of the cartilage; but as there was no blueness of the face and lips, he thought it probable that the hæmorrhage and shock, together with the state of mental depression which his history disclosed, also took their share in hastening the fatal termination.

The history of his case, as revealed at the Coroner's inquest, was as follows:—He was married on the day previous to that of his death to a young woman of his own religion. They retired at about half-past eleven at night. He appears, during the night, to have thrice vainly attempted to consummate his marriage. During the whole night, as indeed during the previous day, he manifested a marked restlessness and anxiety, getting up from the bed, and walking about many times in the night. The last effort he seems to have made at the completion of his object preceded the act of suicide by about half an hour. At half-past seven his wife missed him from her side, was attracted by groans in an adjoining apartment, procured assistance, and found her husband lying on his face, a razor under his head.

CASE OF SUDDEN DEATH: ULCERATION OF THE STOMACH: GALL-STONES.

Narrated by Dr. Russell as follows:—

"The preparation was given me by my friend, Mr. Simons, who treated the case after the patient had passed from under my care."

J. K., aged 69, came under my care as a patient of the General Dispensary, May 22. He was suffering from pain across the epigastrium, occasionally aggravated by paroxysms of great severity. During the period of his attendance he once reported to me that he had vomited a considerable quantity of blood. I examined him carefully, but could not detect anything to explain the pain. He continued under me for about twelve weeks, without much improvement; from the paroxysmal nature of the attacks of severe pain, and from his description of the nature of the pain, I was led to ascribe it to the presence of gall stones; but his cachectic appearance, and his emaciated condition often suggested to me the suspicion of some malignant disease. My treatment was chiefly of a tonic character, with opiates to relieve the pain. He was greatly reduced in circumstances by his illness. Subsequently he was attended by Mr. Simons, who thus reports the conclusion of the case:—

He came under my care in October, with symptoms of pericarditis; he also complained of occasional violent pains in the region of the liver; he had been under medical treatment for the last two years. When the violent pains in the side came on he found most relief from lying down over two chairs. He continued in the same state until Monday, December 19th, when upon returning from the relief station he complained of feeling faint, sat down in the chair and expired. About four months back he vomited about half-a-pint of blood, and twice since in smaller quantities.

Post-mortem.—Heart large, soft and flabby, with about two ounces of liquid blood in its cavities; lungs emphysematous; liver very large, but healthy in appearance; about eight or nine gall stones in the gall bladder, and one impacted in the duct; the stomach contained about half-a-pint of gruel; the coats thickened, and at the upper and back part, at the smaller curvature, about mid-way between the openings, there was an old ulcer through the coats. There was no effusion into the cavity of the abdomen, and I am of opinion that the perforation was completed in taking out the stomach.

The ulcer now presented to the Society will be seen to be of considerable size, oval, its largest diameter about that of a shilling. The mucous membrane is very much puckered, forming long wrinkles radiating from the circumference of the ulcer; externally the appearance of the perforation favours Mr. Simons' opinion, that a cellular layer which probably closed the ulcer, was ruptured in the course of the *post-mortem*, but it is evident that a fatal rupture could not have been long deferred had the patient lived. The mucous membrane having been dissected off, the muscular coat is seen greatly hypertrophied, forming for some distance around the ulcer a layer of considerable thickness, in which the course of the muscular fibres is very distinct, presenting a close resemblance to voluntary muscular fibres. The organic fibres were very distinct under the microscope. This coat gradually diminished in thickness at a distance from the ulcer. In the same part of the stomach the submucous cellular tissue was hypertrophied to a corresponding degree, forming a dense, white, fibrous layer, like a fascia. Fat had been deposited to some extent around the ulcerated portion, in the external cellular tissue.

Dr. Russell remarked on the attacks of hæmorrhage from the stomach on three occasions. The situation of the ulcer was at the smaller curvature, near the coronary vessels, and it is probable that one of their branches furnished the blood. In this respect this case of ulcer of the stomach differed from others which had been before the Society in the course of last year, and also in the patient being an elderly man. The other cases referred to were in females, mostly young, and more or less chlorotic, and the greater tendency of these ulcerations to occur in such subjects was made the subject of remark. It is curious, moreover, that in all our four cases last year, the situation of the ulcer was in the anterior wall of the stomach, in this respect also differing from the case now presented.

Presented November 2nd, 1848.

CANCER OF THE PYLORUS.

Mr. Wickenden presented a very fine specimen of gelatinous cancer of the pylorus:—

Mrs. —, aged 44 years, of delicate health from childhood. Catamenia occurred first about the usual time, and except during her pregnancies, and whilst suckling, occurred with regularity. Suffered for more than ten years from indigestion; has had several children; two are alive; they are delicate, but not unhealthy. The last two or three years (since she has ceased to bear children, and the last was born four years ago,) she has had much water-brash, and vomiting of food. For a long time the vomiting has been effected without difficulty or disgust; the appetite has been good, and many meals have been taken most days. The food has been voluntarily ejected in a few minutes afterwards, in consequence of the pain it caused; she was, however, impatient of restraint in diet, and when for a time she was induced to live upon milk, with lime water and whey, with rüsk, she could not say that she felt more comfortable. The capacity of her stomach seemed prodigious from the fact of her sometimes vomiting two washhand basons full of half-digested food at a time, during the last year of life she occasionally vomited blood, and the matter thrown up, however abundant, usually was of dark colour. No tumour could be distinguished in the abdomen during life, nor pain on pressure at the pit of the stomach. She became extremely emaciated and died anasarcos in October, 1848. The patient always ascribed her stomach affection to a long confinement to bed in consequence of compound fracture of the leg and ankle-joint caused by the overthrow of her carriage.

Autopsy.—External appearance of the body:—Extreme thinness; anasarca; a tumour distinctly to be felt, and its site perceived through its abdominal parietes; every trace of fat gone. *Thorax:* Lungs and heart healthy. *Abdomen:* Stomach very large and contained about a pint of food, the stomach did not lie across the abdomen, but occupied entirely the left hypochondrium, so that the long axis of the stomach was as nearly as possible in a line with the œsophagus; the coats of the stomach were much thickened and the pyloric orifice so nearly closed as to admit with difficulty a small crow-quill, this extremity of the stomach was occupied by a soft tumour of the magnitude of a large walnut, and near to it might be seen considerable thickening of mucous membrane,

elevated into masses similar in structure to the tumour; from the whole of them could be seen blood exuding; the small and large intestines were healthy, as well as every other organ in the abdomen. *Pelvis:* The whole curve of the uterus was preternaturally hard, and the mucous membrane of the os uteri was very red in consequence of the numerous and highly injected state of its blood vessels.

Foreign Department.

ABSTRACT OF THE PROCEEDINGS OF THE ACADEMIE DE MEDECINE, PARIS.

DISCUSSION ON CHLOROFORM.

The present sitting has witnessed the termination of the discussion on chloroform, and its results may be summed up in the following general conclusions:—

1. Chloroform is a powerful poisonous agent, which ought not to be used except by experienced persons.
2. It is, both by its odour and action, an irritant of the bronchial membrane, and therefore requires to be used with great caution when there is any affection of the heart or lungs.
3. Chloroform possesses a peculiar poisonous effect, which if prolonged beyond a certain period is capable of destroying life.
4. More danger accrues from certain modes of exhibiting this agent than from the agent itself.
5. This danger may be avoided by the following precautions:—1, to use pure chloroform, and in moderate doses; 2, to explore the condition of the thoracic organs previously to its exhibition; 3, to take care that a sufficient quantity of atmospheric air is respired with the chloroform; 4, to suspend the inhalation as soon as the patient becomes motionless; 6, not to exhibit it until digestion is completed.

FUNGUS OF THE SPINAL DURA MATER.

M. Bouvier communicated a case of *fungus of the spinal dura mater*. The patient was a female aged 64, who entered the hospital for incomplete paraplegia, which had come on gradually, and without obvious cause. Sensation and motion were partially abolished in both limbs, but more particularly so on the left side. She had command over the bladder and rectum at first, but subsequently the bladder was paralysed, and the urine required to be drawn off daily. The paralysis rapidly increased, and both legs were the seat of severe cramps. The patient died at the end of two months.

On opening the spinal canal the *dura mater* about the tenth dorsal vertebra was elevated by a small tumour, the size of a nut, situate on the posterior aspect of the medulla, and to its left side; its consistence was moderate, of a whitish colour, and in all respects similar to encephaloid cancer. The spinal marrow was sensibly compressed, and pushed on one side. The other organs of the body were sound.

ABSTRACT OF THE PROCEEDINGS OF THE ACADEMIE DES SCIENCES, PARIS.

CAUTERIZATION IN POISONED WOUNDS.

M. Parchappe communicated a note on the effects of cauterization in virulent inoculation, in answer to the remarks of M. Renault, on the uselessness of this treatment in canine rabies. M. Parchappe failed to establish its prophylactic powers in the case of animal poisons, as all his experiments were with strychnine, a poison of a totally different nature.

M. Hervier presented a memoir on the exhalation of carbonic acid in health and disease. (See a former number, p. 191, in which the conclusions are given among the articles in the "General Retrospect.")

IODIDE OF POTASSIUM AS A REMEDY FOR THE POISONOUS EFFECTS OF LEAD AND MERCURY.

A paper by M. Natalis Guillot, on the use of iodide of potassium as a remedy for the poisonous effects of mercury and lead, was also read. The most interesting portion of the communication is that in which the author shews that the injurious effects of lead may be rapidly removed by small doses of the iodide, while a large dose appears to increase its poisonous properties. The experiments were made on dogs. Their explanation of the *modus operandi* of the iodide is, that it forms a soluble salt with the mercury and lead, which are thus readily eliminated.

An interesting notice was also given of the existence of the practice of anæsthesia for operative purposes, as well as of hydropathy, among the Chinese, as early as the sixteenth century.

USE OF THE PANCREATIC FLUID.

M. Bernard presented his important memoir on the uses of the pancreatic fluid. [This has been already published entire in a former number of this Journal.]

Some other communications of trifling interest were also presented.

THE PETITION OF MEDICAL OFFICERS OF UNIONS IN ENGLAND AND WALES.

The humble Petition of the Chairman and Committee of the Medical Officers of Unions in England and Wales, and other Members of the Medical Profession,

Sheweth,

That your Petitioners have been duly authorised, by resolution passed at a meeting of delegates and others representing the medical officers of unions in England and Wales, held at the Hanover Square Rooms, on the 19th of February, 1849, to lay before your Honourable House a statement of the grievances complained of by the said medical officers, and to solicit the interposition of your Honourable House for their redress and removal.

That your Petitioners have already, by memorial to the Right Honourable the Secretary of State for the Home Department, and to the President of the Poor-

Law Board, respectfully set forth the numerous evils and defects of the present system of administering medical relief to the sick poor, more especially as they affect the position and interest of the medical officer; but your Petitioners lament that hitherto no decisive steps have been taken towards their amendment, either by the Government or the Legislature; they therefore entreat the attention of your Honourable House to the manifold injuries which they sustain under the existing laws.

Your Petitioners desire to impress upon your Honourable House their conviction that very much of the difficulty and dissatisfaction attending the operation of the poor laws originates in the present mode of affording medical aid, for it will appear, on examination of the facts, that almost every case of complaint that has strongly agitated public opinion has been contingent on the imperfect arrangements in this important branch of poor-law administration. Among the defects of this system bearing more directly on the well-being of the destitute poor, the following are the most obvious and important:—

1st. The difficulty of obtaining an order for medical relief from the relieving officer in cases of sudden illness, of accident, or of midwifery.

2nd. The frequent refusal and general uncertainties of remuneration to the medical officer for his attendance on a poor patient under such circumstances, and the consequent hardship either to the patient, the medical officer, or both.

3rd. The undue restriction on the medical officer in reference to his power of ordering the necessary aliment for the cure of his patient, and the frequent neglect of such orders when given.

4th. The want of the requisite inspection over the working of the system by intelligent and duly qualified medical men.

That there can be no doubt that in consequence of the present complicated and inefficient system much avoidable suffering and distress afflict the labouring classes; and that, by invaliding the father of a family, and throwing him, his wife, and children upon the funds of the Union for support during a protracted disease, and by the increased expenditure arising from premature widowhood and orphanage, the burdens on the ratepayers are greatly augmented; whilst, also, the same causes tend to increase that rapidly-spreading mass of hereditary pauperism which is confessed to be a national calamity, which has brought the Poor-laws themselves into very general disrepute and distrust.

That, whilst your Petitioners deplore these evils, they feel it their duty to state that the medical officers are worked heavily and at great disadvantages, and, although, as it has been generally avowed, they perform their trying and onerous duties with zeal and humanity, they have nevertheless universally complained of the grievous pressure of the system under which they act, and of the want of encouragement to exertions, hitherto so faithfully rendered, which they experience in the disgracefully low and parsimonious remuneration at present awarded.

That your Petitioners have ascertained, after an examination of returns from 805 districts in various

parts of the country, that the average payment per case for medical attendance on the poor is only 2s. 7d. for the country district, and 1s. 6³/₄d. for the metropolitan districts, the highest of which sums is scarcely sufficient to defray the reasonable cost of drugs at the rate of expenditure that obtains in hospital and dispensary practice, and affords not the slightest recompense for the surgeon's skill, time and labour, which in an extensive and populous district are so fully engaged, that he is greatly impeded in his efforts as a private practitioner, and he sustains in this respect a heavy loss, of which he becomes sensible only when it is too late to redeem it. That it is also proved that, in consequence of the salaries being fixed upon no definite plan, the payment for medical service varies very widely in different districts, being so high in the Bishop Wilton district of the Pocklington Union as 14s. 4d. per case, and so low in a district of the Newton Abbott Union as 3d. per case; that also, the remuneration is frequently in an inverse ratio to the amount of work done, and instances are known to your Petitioners where one medical officer doing ten times more work than another receives only one-fourth of the remuneration per case. Similar inequalities prevail even in different districts of the same Union, in consequence whereof great injury has been done to many hard-worked and meritorious officers, and the liveliest dissatisfaction has been expressed throughout the country. Your Petitioners would also beg the attention of your Honourable House to the fact, viz., that the civil surgeon attending a detachment of the army receives 6s. 6d. per head, sick or well,—a sum that would afford remuneration of several pounds for each sick case; also that 13s. 7d. is paid for a sick felon who is attended in a jail, whereby the time of the surgeon is not wasted, nor is strength impaired, by making extensive and laborious journeys; and that 7s. per head is paid for the police. And your Petitioners trust that the contrast of these payments with the paltry average of about 2s. awarded for medical attendance on the sick poor of this country will present a striking illustration of the wrong and hardship to which the union medical officer is subjected, and will convince your Honourable House of the instant necessity of reforming so unjust and degrading a system.

Your Petitioners further desire to state, that the invidious position in which union surgeons are placed between the rival powers of the honourable the Poor-Law-Board and the Boards of Guardians, operates most disadvantageously to their interests and to the satisfactory performance of their official duties; for, inasmuch as any complaint or misunderstanding that may arise, or any appeal that may be made, involves the liability of coming under the jurisdiction of two conflicting boards, the expectation which the medical officer ought to feel of a just reward from a calm and unbiassed consideration of his case is annihilated by the conditions under which the adjudication is made.

That, moreover, in consequence of this antagonism between the central and local boards, the union surgeons are unjustly deprived of the benefit of those instructions issued in their favour by the Poor-Law Board in accordance with the recommendation of a

Committee of your Honourable House; and your Petitioners beg to adduce the following illustrative facts confirmatory of this statement. That, in the year 1842, the honourable the Poor-Law Commissioners issued a code of regulations to the Boards of Guardians, ordering a scale of payments therein specified to be made to Poor-Law medical officers as extra payments for various surgical operations, and expressly commanded that such extra payments should not be included in the salary of any district medical officer, or contract made by any Board of Guardians, with a district medical officer; yet, despite this express injunction of the Honourable Commissioners, your Petitioners are authorised to state that these instructions have been very generally evaded or disobeyed by the Boards of Guardians; that several of them reduced the salaries of their medical officers, in order that, after the addition of the extra payments, the salaries might not exceed the original amount; others, by undue constraint, induced the medical officer to compound for all extras by a small fixed addition to the annual salary; whilst others have systematically and rigorously evaded the order, by sending all cases of accident to some hospital to which the Board subscribes, and thus the medical officer is deprived of any boon intended by the instructions of the Commissioners, the patient's sufferings are considerably augmented, and even his life often risked by the removal in carts over bad roads for many miles, during perhaps an inclement period of the year.

Notwithstanding the numerous complaints that have been already made, your Petitioners regret to state that the representations of the medical officers of unions have been overlooked, and that by recent Acts passed by your Honourable House, in utter disregard of all their claims, they have experienced additional hardship and injustice.

That the Health of Towns' Act, and the Act for the Prevention of Epidemic Diseases and the Removal of Nuisances, passed by your Honourable House during the last Session of Parliament, confer certain powers on the Boards of Guardians, and the New General Board of Health, in relation to sanitary purposes, in virtue of which the medical officers of unions have been called upon to perform the duties of officers of health, without any provision being made for payment for such duties. As these duties form no part of the contracted engagements of the medical officers with the Boards of Guardians, and are not referred to in the instructions of the Commissioners of Poor-Laws under which the Union Surgeons took office, your Petitioners consider that the orders issued by the Boards of Guardians in compliance with the instructions of the General Board of Health, are a direct violation of the rights of union surgeons as private citizens of the State.

That your Petitioners have already protested to the General Board of Health, and to the Poor-Law Board, against this new imposition of unrequited labour, and do hereby most respectfully repeat their protest to your Honourable House, and earnestly trust that your Honourable House will see fit, not only to amend laws so directly subversive of the rights of the subject, but will also undertake the revision of all other laws which

affect the position of the medical officers of unions, so that a system more conformable with justice and the true interests of the public may be established. Your Petitioners are convinced that under an improved system, equally regardful of the interests of the poor and of the medical officer, prompt and efficient attendance might be obtained in all cases for the former, whilst the just interests of the latter might be guaranteed, and that thereby the requirements of a true economy in the apportionment of the public funds might be secured, and the duties of an enlightened humanity worthily fulfilled.

That, as the principles of a new and improved system, your Petitioners are humbly of opinion,—

1st. That the payment for medical relief to the poor should be made from the Consolidated Fund.

2nd. That the remuneration should be fixed according to a settled plan or scale, and that the average payment in town and country districts should be at least 6s. per case.

3rd. That the appointment of medical officer to a district should be permanent, and subject only to be rescinded by the President of the Poor-Law Board, or by the director of a Board specially appointed, upon proved charge of neglect of duty, gross mal-practice, legal sentence inferring dishonour or crime, or other valid cause.

4th. That a general board should be established for the superintendence of the duties of the medical officers of unions, under a chief medical director, and a sufficient number of competent medical inspectors, to protect both the interests of the public and the profession.

That your Petitioners, seeing the perverse opposition by which the local boards have too often succeeded in rendering the instructions of the central board nugatory and void, are fearful that the Poor-Law Board has not sufficient power to remove the existing evils, and they therefore emphatically press upon your Honourable House the urgent necessity of considering their manifold wrongs and grievances; and your petitioners remembering that nearly 3,000,000 of Her Majesty's subjects are entrusted to their care and skill in every form of accident and disease, that they are often called upon singly, and at a moment's notice, to succour life under the most appalling and hazardous occurrences, and the high qualifications that are necessary from them for a due performance of their varied duties, and considering also the constant liability to pestilence, with all its fearful consequences, not only to themselves but also to their families, the numberless annoyances and harassing anxieties incidental to their arduous and responsible duties, the continual exposure to the vicissitudes of the climate and season, and the daily sacrifice of time, money, and strength, which their avocations necessarily incur, believe that they have paramount claims on the attention of your Honourable House, and they earnestly hope that your Honourable House will speedily take into your consideration their present position and claims, and amend a system so defective, unsatisfactory, and fruitful of injustice to all parties concerned in its operation, whereby your Honourable House will fulfil the noblest

functions of a philanthropic and parental legislature, will enlist the sympathies of the suffering poor, command the respect and confidence of the public, and win the gratitude of a numerous but oppressed body of public officers.

And your Petitioners, in conclusion, further pray your Honourable House that you will take into your consideration, as speedily as can be, and adopt measures to amend, not only the system of Poor-Law Medical Relief, but also to put on a more enlightened and satisfactory footing the laws and regulations relating to the education and control of the medical profession generally throughout England and Wales.

And your Petitioners will ever pray.

THOMAS HODGKIN, M.D.,

Chairman of the Committee.

ADOLPHUS BURNETT.

WILLIAM LOBB.

&c., &c., &c.

MEDICAL LEGISLATION.

MEMORIAL AND PETITION FROM WOLVERHAMPTON.

At a meeting of the medical practitioners residing in Wolverhampton and its vicinity, (convened by public advertisement) held on the 18th of April, at the South Staffordshire General Hospital, Dr. Topham in the chair, the following resolutions were unanimously adopted:—

Proposed by Mr. John Fowke, and seconded by Mr. Edwardes,—

“That this meeting considers that a measure recently proposed to be brought before the Legislature, entitled “Outline of a Bill for Regulating the Profession of Physic and Surgery,” is highly objectionable, as tending to degrade the general practitioners of medicine and surgery in this kingdom, and to prove injurious to the best interests of the public.”

Proposed by Mr. Dehane, and seconded by Mr. Cartwright,—

“That a memorial be presented to Sir George Grey, her Majesty's Secretary of State for the Home Department, together with a petition to the House of Commons, representing the views of the practitioners of medicine and surgery residing in Wolverhampton and its vicinity, in opposition to the creation of a College of General Practitioners, and expressing their conviction that the establishment of such additional Examining Board is totally unnecessary, as the Colleges of Physicians and Surgeons, if properly modified, contain all the elements requisite for examining and licensing in every branch of the profession.”

Proposed by Mr. Haslehust, and seconded by Mr. Coleman,—

“That the memorial and petition which have been read by Dr. Bell, be adopted, and that the memorial be transmitted to her Majesty's Secretary of State for the Home Department: that Mr. Thornley, one of the Members for the borough of Wolverhampton, be requested to present the petition to the House of Commons; and that Mr. Villiers, together with the

members for the southern division of the county, be requested to support the prayer of the petition."

Proposed by Mr. Dunn, and seconded by Mr. Gatis,—

"That the resolutions of this meeting be advertised in the *Lancet*, *Medical Gazette*, *Provincial Medical and Surgical Journal*, and in the *Staffordshire Advertiser*, and *Wolverhampton Chronicle*."

Proposed by Mr. Underhill, and seconded by Mr. Wright,—

"That Dr. Topham, Mr. Edwardes, Dr. Bell, Mr. Gatis, and Mr. Wright be appointed a committee, to carry these resolutions into effect."

Proposed by Mr. Edwardes, and seconded by Mr. Cooper,—

"That the cordial thanks of the meeting be given to Dr. Topham, for his able and efficient services in the chair."

JOHN TOPHAM, Chairman.

South Staffordshire General Hospital,
April 18, 1849.

GLOUCESTERSHIRE MEDICAL & SURGICAL ASSOCIATION.

To the Right Honourable Sir George Grey, Bart., M.P.,
Her Majesty's Secretary of State, &c., &c., &c.

The Memorial of the Council of the Gloucestershire Medical and Surgical Association,
Sheweth,—

That your Memorialists, in conjunction with the members of the Association which they represent, have for many years taken a deep interest in the important question of Medical Reform, and have from time to time memorialised the Crown and the Government on this subject.

Your Memorialists are of opinion that one of the evils of the medical profession is the number of corporate bodies empowered to grant diplomas and licences;—that the Colleges of Physicians and Surgeons of England, if rightly organized, are sufficient for the requirements of the profession and the public in this country;—that the proposed creation of a new institution for the enrolment of General Practitioners is uncalled for by any necessity, and that the establishment of another College, whilst it would increase the existing evil of corporate monopoly, would fail to effect the objects for which it was concerted.

That your Memorialists have read with much satisfaction a Memorial presented to you by the medical men of Manchester, in reference to certain "Outlines of a Bill for the regulation of Physic and Surgery," proposed by a conference of parties representing the Metropolitan Corporations and the National Institute.

Your Memorialists desire to record their approbation of the views and principles embodied in the *Manchester Memorial*; and they respectfully urge their truthfulness and importance upon your serious consideration.

Signed on behalf of the Council of the Gloucestershire Medical and Surgical Association.

T. WRIGHT, M.D., Cheltenham, President.
J. W. WILTON, Gloucester, Hon. Sec.

General Retrospect.

SURGERY.

REPEATED PUNCTURE OF THE BLADDER IN CONSEQUENCE OF RETENTION OF URINE.

By M. Velpeau.

A man aged 60 years had been lately admitted for treatment, with complete retention of urine for some days, caused by a stricture of long standing in the urethra. Repeated attempts having been made without effect to introduce catheters and bougies, M. Velpeau hastened to puncture the bladder above the pubes. There was nothing particular in the operation; the bladder was emptied, the patient relieved, and a gum elastic catheter left in the opening. On the following day, (or the third day,) the instrument was displaced from the bladder by some hasty movement of the patient and the condition of retention reproduced; M. Velpeau had then to repeat the operation, and this was done forty-eight hours after the first. The original opening had been made in the median line, a little distance from the pubes; the second was made upon the right side about two inches from the first. A long gum elastic sound was left as before, in the opening, and due precautions taken to prevent a recurrence of the accident. The operation was performed five or six days ago, and the patient does not appear to be going on badly, but the hypogastric region is hard. Is this hardness the result of an effusion of urine occurring after the escape of the instrument, or of partial peritonitis independent of this cause? At this moment it is impossible to say. M. Velpeau endeavours each day to pass small bougies through the natural passage, but the contraction is such that these instruments are at present unable to overcome the obstacle, and he is content to have a bougie pressing against the stricture since he is unable to pass one beyond it.—*Annales de Therapeutique*, Mars.

MALIGNANT ULCERATION OF THE THUMB IN A CHILD: CURE BY THE USE OF CREOSOTE.

A child, 5 years of age, of delicate constitution, and remarkable intelligence, was pricked in the thumb of the right hand by the point of a brace buckle; suppuration ensued, succeeded by a phagadenic ulceration, which in a short time destroyed the extreme phalanx. It extended thence to the next phalanx, which in its turn became disorganized, necrosed, and expelled. The disorder then spread to the soft parts in the metacarpal region of the thumb, and threatened them in the same way. In this stage it was brought to the hospital. On examining the stump there was found an ulcerated surface about the size of a two-franc piece, with a deep base, greyish and foul, surrounded by a red disc, and painful. Cauterization with nitrate of silver, the acid nitrate of mercury, and even the red-hot iron, was tried without effect. Whilst hesitating some days respecting amputation, and also trying the effect of various remedies, it was determined, as a last resource, to apply fomentations of pure creosote. The effect produced was remarkable; on the following day the ulcer was

no longer painful, its surface had ceased to spread, and was of a bright red colour; in a few days the wound cicatrized, and the little patient was cured. The metacarpal bone below the cicatrix is evidently swollen.—*Annales de Thérapeutique*, Mars.

CREOSOTE GARGLE IN MERCURIAL SALIVATION.

Dr. Faulcon narrates the following as an instance of a successful mode of treating mercurial salivation:—

On the 25th of September, 1842, I was called in consultation to J. S., who was suffering from severe salivation, and as some of the usual remedies in such cases had been used without benefit in this disease, (for such it certainly is,) and as the muscles of the jaws were rapidly stiffening, so as scarcely to permit his speaking with distinctness, I suggested to his attending physician the use of the following gargle:—Creosote, half a drachm, sage tea one pint. To be used every hour during that day, and its effects accurately noted. In thirty minutes after its first application he felt a sharp tingling sensation along the angles of both jaws, and a slight convulsive motion in the muscles of the lower jaw. Shortly after the appearance of this last sensation, there was a marked relaxation of all the muscles of the face, and he expressed himself as feeling better (locally,) than he had done for many days. In the evening there was a very great decline of the salivary discharge, and a great improvement in the appearance of the mucous membrane of the mouth and palatine region, which, prior to its application, wore that aspect so indicative of a near approach to sloughing. A few days continuance of the gargle effected a complete recovery.—*Philadelphia Medical Journal*, November.

OBSTETRIC MEDICINE.

TREATMENT OF HYDROCELE IN INFANTS.

Dr. Coley states that he at one time believed that all cases of hydrocele in infants were curable byunction with compound mercurial liniment, or by a lotion of muriate of ammonia. A wider experience has convinced him that many cases will resist such treatment, but he has found that such may be speedily cured by the application of leeches, which he is induced to apply, from the idea that the fluid is produced by an inflamed state of the tunica vaginalis.—*Obstetric Record*, Feb. 1st, 1849.

TOXICOLOGY.

POISONING BY OPIUM: GALVANISM.

Mr. Stiff records the following case in the *Lancet* of March 24th:—He was summoned to a woman aged 54, in a state of coma. She was insensible, with bloated face, greatly contracted pupils, relaxed muscles, pulse 100, feeble. The stomach pump was used, and the contents of the stomach exhaled a strong odour of opium. A mixture of compound spirit of ammonia and lavender was injected. At five p.m., no visible improvement having taken place, electro-galvanism was resorted to. The currents were variously applied by the sponge, for half an hour, to the diaphragm, spine, axilla, sacrum, legs, and face. The effect was striking: the involuntary action first induced was succeeded by decided evidence of occasional

consciousness; resistance was also offered to the moving of the arm, and she turned on her side and back alternately. We now desisted for ten minutes. Neither the strong sinapisms nor the ammonia liniment had produced any effect; the mouth was now firmly shut, and she began again to relapse into complete insensibility. The galvanism was resumed for half an hour or more, but its effect was by no means so great, and she seemed to be sinking. Coffee was swallowed. At eight p.m., some improvement, as warmth and consciousness, were noticed. Galvanism applied every ten minutes with increasing benefit. Ten p.m., had taken a breakfast-cup of coffee, and pulse rallying. The improvement continued but consciousness was very imperfect until leeches were applied to the temples, after which the amendment became very perceptible and persistent. The case is reported as an instance of the important benefit derived from galvanism under appearances of the most unpromising kind.

POISONING BY SULPHURIC ACID INTRODUCED INTO THE RECTUM.

M. Pinjon, of Saint Etienne, has given in the *Journ. de Méd., de Lyon*, a detailed account of the history of a case in which a wife attempted to destroy her husband, first by poisoned wine, and then by the use of enemata, containing sulphuric acid. The symptoms, as might be anticipated, were those of extreme irritation of the bowels within, and of the external parts adjacent to the anus. The case was treated without any suspicion of the cause of the patient's sufferings; nor was the real nature of the case discovered till three months had expired. About the fourteenth day from the commencement of the symptoms, a portion of intestine was passed by stool, after which the amendment, though very slow, was gradual, and a complete recovery took place. The event occurred in the end of 1844, and four years after the man (Maisonneuve,) was examined by M. Pinjon, and found to enjoy good health, though with some peculiarities in the action of the bowels. The account before us does not enter into any detail of the evidence on which the charge of poisoning is founded, reference being made only to the effect produced on the straw of the chair on which he sat when the first enema was administered, and on the curtain of the bed on which he lay where the second was used.

Two cases besides are referred to in which sulphuric acid was thrown into the rectum, and yet recovery for the time took place, one detailed by M. Fouquier, in the *Gazette des Hôpitaux*, 1846, p. 575, the other in the *Annales de Thérapeutique*, Vol. ii., p. 457.—*Annales de Thér.*, Dec., 1848, Jan., 1849, and *Month. Journ.*

CASE OF POISONING BY CREOSOTE.

On January 17th, Mr. Macnamara, was called to see Mrs. M—, the wife of a respectable tradesman, and on his arrival at the house, he found her presenting the following symptoms:—She was lying in her bed in a state of profound stupor, from which she could with difficulty be aroused for a few minutes, but only again to relapse into her former state of unconsciousness. Her countenance was fuller and more flushed than it naturally appeared. Her eyes were fixed,

but the pupils were neither dilated nor contracted. The pulse was slow and laboured; the heart's action remarkably slow and weak; the stomach was inclined to be sick, and the ejecta bore a strong smell of creosote. When aroused, her chief complaints were of vertigo and general uneasiness in the head, as also of burning pain along the œsophageal track, and in the stomach. On inquiry, he ascertained that for the last twenty-four hours, she had been suffering severely from toothache, to relieve which she had recourse to creosote, in the application of which she had been most unsparing, and that her present symptoms had gradually supervened, increasing in intensity up to the period of his arrival.

The treatment adopted consisted of the employment of mustard emetics, sinapisms over the cardiac and epigastric regions, with copious dashings of cold water in the face; the indications being, in the writer's opinion, to remove the poisonous effects of the creosote by the exhibition of medicines that would rouse the vital energies of the patient, at the same time that it removed from the stomach any of the creosote that might have accidentally found its way there. This line of treatment was attended with the happiest results; the stupor was completely removed, and the only symptom that remained was severe pain in the stomach, which was completely relieved by the administration of an anodyne draught, and the patient recovered without any other untoward symptoms than those consequent on a slight febrile disturbance, which rapidly yielded to antimonials, followed by purgatives.

The circumstance that renders this case most interesting, is the extreme rarity of cases of poisoning by creosote, no other case that the writer is aware of having occurred, but one which unfortunately proved fatal, and the particulars of which have not been preserved. It is recorded in the *Liverpool Mercury*, and transferred thence to the columns of the *Times*, June 17, 1839, and it is referred to by Dr. Pereira, in his talented work on the *Materia Medica*. This case differs from that which is here brought forward in this particular, that a large quantity, amounting to two drachms, had been swallowed. In this case the writer attributes the injurious effects that ensued more to the prolonged inhalation of the creosote than to the actual quantity that got into the stomach; that some, however, did get into that viscus, is, in his opinion, evidenced by the great pain referred to the stomach and œsophageal track. Another interesting feature in this case, and one that might seem to give some colour to the doctrine of *similia similibus curantur*, is the presence of vomiting, creosote being so vaunted for its power in allaying that symptom. The vomiting, however, is clearly referable to the irritating effects that the creosote produced on the coats of the stomach.—*Dublin Medical Press*, March 7th.

MEDICAL JURISPRUDENCE.

NEW SIGN THAT A CHILD HAS BEEN BORN ALIVE.

Dr. Virchow has announced that the presence of uric acid in the kidney, which may be detected with the naked eye, is conclusive of a child having been born alive. His conclusions are—

1. That uric acid deposit is never found in children born dead, or who have died within forty-eight hours after birth.

2. That the deposit does not occur before forty-eight hours after birth.

3. That it is not generally found later than the twentieth day after birth.—*Medical Times*, Jan. 20th.

Medical Intelligence.

TESTIMONIAL TO JOHN FOWKE, ESQ.

A gratifying instance of the estimation in which members of our profession are sometimes held by their immediate patients and friends, has recently occurred at Wolverhampton. The extraordinary sum of £1583 has been raised by subscription, and presented to Mr. John Fowke on his retirement from the duties of the General Dispensary, as a testimonial from the subscribers of "their estimation of his high medical character and abilities, and of the disinterested manner in which they have always been applied to the benefit of the community."

LIFE-ASSURANCE OFFICES.

REMUNERATION OF MEDICAL MEN FOR THEIR REPORTS.

In the list of Life-Assurance Offices which have adopted the principle of remunerating medical men, as given in a late number of the *Journal*, the Medical Legal and General Mutual Life Office, 126, Strand, London, who pay a fee of one guinea for every certificate, *whether favourable or not*, was accidentally omitted.

ROYAL COLLEGE OF SURGEONS.

Gentlemen admitted members Friday, April 13th:—J. A. S. Addison, R. W. Broster, G. A. Sheppard, J. B. Sheppard, J. German, T. B. Kenderdine, C. M. Smith.

Friday, April 20th:—E. W. Mayne, J. F. Pritchard, H. E. Brameld, A. Law, W. Tidmas, J. C. Lynch, W. Tomlin, E. Younge, W. Harrison, T. O'K. Gordon, C. A. Allen, H. Briggs.

The following gentlemen, all members of the College, were admitted Fellows at the meeting of the Council on the 11th of April:—Edgar Barker, Edgware Road, (diploma dated March 5th, 1824); Henry Butler, Hobart Town, Van Dieman's Land, (July 28th, 1843); William Henry Colborne, Chippenham, (July 17th, 1846); John Cooper Forster, Wellington Street, Southwark, (November 15th, 1844); John Havers, Bedford Place, Russell Square, (December 15th, 1837); Thomas Brooks Larkins, Hon. East India Company's Bombay Service, (December 23rd, 1836); and Arthur Sarjeant, Meriden, Warwickshire, (Nov. 19th, 1841.)

SOCIETY OF APOTHECARIES.

Gentlemen admitted Licentiates Thursday, April 12th, 1849:—Edward Batt, Witney, Oxon; Henry William Beriase, Helston; Herbert Brown, Tonbridge;

John Davis, Wreckenton; Francis Edward Goldsmith, Boston; Griffith Hooper Griffiths, Cheltenham; John Robinson, Midhurst; Arthur Rudge, Fakenham; James Cummin Toshack, South Shields; Charles Augustus West, Camelford, Cornwall.

Gentlemen admitted Licentiate Thursday, April 19th, 1849:—James William Crow, Gorleston, Suffolk; John Clarke, Greenham, Berks; Frederick Duke, Hastings; Philip William Govett, Plymouth; John Higginbottom, jun., Nottingham; Thomas Hutchinson, Camborne, Cornwall; James Newnham, Lyme Regis; William Matthew Sheppard, Fulham; Isaac Tucker, Westbury, Leigh; David Morris Thomas, Cwmaman, Carmarthen; Edmund Whitaker, Bacup, Lancashire; Thomas John Warburton, Betley, Staffordshire.

OBITUARY.

Died, January 17th, at Graham's Town, Cape of Good Hope, in his 34th year, Edward Russ, Esq., surgeon, late of Castle Cary, Somerset.

April 10th, at Nuneaton, in the 79th year of his age, John Bond, Esq., surgeon.

April 22nd, at Delph Cottage, Cheshire, aged 61, Brereton Nightingall, Esq., formerly resident surgeon of the Liverpool Fever Hospital and Workhouse.

April 23rd, W. Warden, M.D., surgeon to Her Majesty's Dock Yard, Chatham, in his 72nd year.

Lately, Dr. George Gardener, Superintendent of the Botanic Garden, Peradenia, Kandy, Ceylon.

BOOKS RECEIVED.

The Dependancies of Animal Motion on the Law of Gravity. By Henry Wigglesworth, M.B., &c. Part II. London: Bailliere. 1849. 8vo. pp. 210.

Lectures on the Causes and Treatment of Ulcers of the Lower Extremity, delivered at the London Hospital, during the Summer of 1848. By George Critchett, Esq., F.R.C.S., Surgeon to the Royal London Ophthalmic Hospital, &c. London: Churchill. 1849. 8vo. pp. 121.

Parturition, and the Principles and Practice of Obstetrics. By W. Tyler Smith, M.D., Lond., Lecturer on Obstetrics in the Hunterian School of Medicine. London: Churchill. 1849. Fcap. 8vo., pp. 395.

A Short Sketch of the Life and Writings of the late Joseph Clarke, Esq., M.D., Vice-President of the Royal Irish Academy, and formerly Master of the Dublin Lying-in-Hospital, &c. &c. By Robert Collins, M.D., President of the King's and Queen's College of Physicians in Ireland, formerly Master of the Dublin Lying-in-Hospital, &c. &c. London: Longman. 1849. 8vo. pp. 88.

Anæmia, and its Consequences: Enlargement of the Thyroid Gland and Eyeballs. By James Begbie, M.D., F.R.S.E., Fellow of the Royal College of Physicians, and Vice-President of the Medico-Chirurgical Society of Edinburgh. (Read to the Medico-Chirurgical Society of Edinburgh, 3rd January, 1849.) Edinburgh: Sutherland and Knox. 1849. 8vo. pp. 15.

Questions and Observations in Hygiene, &c. By F. James Brown, M.D., Lond., &c., Assistant Surgeon R.N. London: Churchill. 1849. pp. 64.

Report of the Epidemic Cholera, as it has appeared in the territories subject to the Presidency of Fort St.

George. By William Scott, Surgeon, &c. Edinburgh: Blackwood; London: Murray. 1849. 8vo. pp. 212. Map.

Practical Observations on the Prevention, Causes, and Treatment of Curvatures of the Spine, &c. By Samuel Hare, surgeon. Third edition. London: Churchill. 1849. 8vo. pp. 245. Plates.

A Practical Treatise on Morbus Coxarius, or Hip-Joint Disease, &c. By William C. Hugman, M.R.C.S., Surgeon to the Verrall Institution for the Treatment of Spinal Diseases and Distortions, &c. London: Highley. 1849. 8vo. pp. 81. Plates.

Proceedings of the Westminster Medical Society. Session. 1848-49. 8vo. pp. 20.

Hints on Obstetric Practice, with Illustrations. By John Brenner, surgeon, Newtyle. Part I. Edinburgh: MacLachlan and Stewart. 1849. 8vo. pp. 98.

On Healthy and Diseased Structure, and the true Principle of Treatment for the Cure of Disease, especially Consumption and Scrofula, founded on Microscopical Analysis. By William Addison, M.D., F.R.S., Licentiate of the Royal College of Physicians. London: Churchill. 1849. 8vo. pp. 320.

The Medical Remembrancer, &c. By Edward B. L. Shaw, M.R.C.S., and L.A.S. Third edition. London: Churchill. 1849. pp. 108.

Lectures on the Parts concerned in the Operations of the Eye, and on the Structure of the Retina, &c. By William Bowman, F.R.S., F.R.C.S.E., &c. London: Longman. 1849. 8vo. pp. 143. Illustrations.

PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION.

ANNIVERSARY MEETING.

The Anniversary Meeting of the Provincial Medical and Surgical Association is appointed to be held at Worcester, on Wednesday, August 1st, and Thursday, August 2nd, when Chas. Hastings, M.D., of Worcester, will preside.

NOTICE TO MEMBERS.

Gentlemen who have not yet paid their subscription for the current year, or who are in arrears, are requested immediately to forward the amount due, either to the Treasurer or Secretary of the Association, as the accounts are now about to be made up for the Annual Meeting.

ROBERT J. N. STREETEN,
Secretary.

ERRATUM.

Page 206, col. 2, line 24, for "I should think it desirable to bleed," read "I should think it not desirable, &c."

TO CORRESPONDENTS.

Communications have been received from Mr. H. Williams; Mr. Humpage; Mr. F. S. Garlick; Dr. Copeman; Æsculapius; Mr. Colthurst; Mr. Bartrum; Mr. G. Edwards; Mr. Markwick; Dr. Banks; Mr. Freer; Mr. Swayne; Mr. Wilton; Mr. Cornish; Dr. Simpson; Mr. Kelson.

PROVINCIAL MEDICAL & SURGICAL JOURNAL.

ON ANTEVERSION OF THE UTERUS.

By SAMUEL EDWARDS, M.D.,

Formerly Resident Medical Officer to the Edinburgh General Lying-in Hospital, and late Physician to the Eastern Dispensary of Bath, and to the Bath Ear and Eye Infirmary, &c.

In a science of such vast importance to the well being of mankind as that of medicine, whenever there exists a doubt as to theory or practice, all will allow it to be an imperative duty incumbent upon every true lover of his art or of his kind, to state all such facts, as, arising within each one's own experience, may tend to prove or disprove the existence of a disease, and relieve it, if possible, from the imputation of being a mere *vexata questio*; and by establishing it amongst the list of those ills to which the human frame is liable, assist at the same time in the discovery of a ready diagnosis and a philosophical mode of treatment. For this reason I am desirous of recording the particulars of a case of anteversion of the uterus which has occurred to me subsequent to one which I published in the pages of the *Lancet* in the year 1846. In that paper I was led to make the following remark:—"The recital of numerous cases of anteversion of the uterus, has at length, I believe, settled the question as to its existence at all, in the minds of almost all medical practitioners; and although it must be allowed that it is an affection, in its full extent, rarely met with, and requiring most careful examination, (especially in its earlier stages, when it may indeed be passed over by the physician, and be by the patient unheeded,) for its correct diagnosis, yet, from frequent opportunities of investigation, I am convinced the displacement, in a slight degree, is of more frequent occurrence than it is usually considered." Since that time, I have, however, met with several gentlemen of great experience in their profession, who, because the disease has not been thrust prominently before their eyes, have been led without taking the trouble of investigating their cases deeply, to doubt the existence of such a malady at all. I am quite aware that when the disease exists only in a slight degree, the symptoms are neither very disturbing to the patient nor prominent to the practitioner, especially if of superficial perceptions; and in more severe cases, those symptoms, when seen, may

be saddled upon other maladies. Still a careful examination per vaginam, will readily disclose the nature of the disease, and if an attempt be made to examine the "os uteri" with the speculum, a difficulty will be experienced and not to be overcome, which will declare the fact of, at any rate, an altered position in the uterine body and neck.

The patient referred to, Martha E., a poor woman, married, aged 31, but without children, of a large frame, but thin, and lymphatic in temperament, applied to me for advice in September 1847. She had been married four years, and during this time had been regular in her monthly periods until the last nine months, which had at first induced her to believe herself pregnant; still a complete cessation had not taken place, only a great diminution in quantity, which was also altered in quality. Soon after, she began to complain of pain and weakness in the lumbar region, with a sense of "bearing down," also heat and weight over the pubes and in the groins. This continued between six and seven months when additional symptoms made their appearance and remained up to my first seeing her. Leucorrhœa, of a yellowish hue and tenacious in consistency, set in, occasionally streaked with a little blood; a sense of fulness about the rectum which was always distended more or less from fecal accumulations, she being generally obliged to resort to aperient pills before obtaining relief from the bowels. That, however, which most annoyed her, was the irritation about the bladder and the almost constant desire to pass urine, with a difficulty and pain in so doing. This latter was so severe and troublesome as to be the chief cause of her applying for relief, especially as it had been increasing the previous fortnight. Almost all her symptoms, she stated, were relieved by the recumbent posture; walking affected her a good deal, but standing still, or straining at stool, and also urinating, always produced great increase in her distress. Her general health is not good; her face is pale and anxious, and to use her own phrase, she "is almost tired out" by the constant uneasiness. Complaints of various symptoms of dyspepsia,—e. g., flatulency, nausea, and sense of weight and uneasiness at the epigastrium immediately after eating. The tongue is flabby, indented by the teeth, and coated with a creamy-looking fur; for more than a week past the breasts seemed to have sympathized with the irritable condition of the uterus,—having become fuller than usual,

accompanied with darting pains, especially at night. On considering over the above symptoms I was led to believe that it was a case of ulceration of the neck of the uterus, and that the irritability of the bladder might be owing to other causes. The urine gave out a copious deposit of the alkaline lithates. On examination, I found the vagina of higher temperature than usual; the finger could with very great difficulty reach the cervix, the extremity of which was directed upwards and backwards towards the sacrum, so much so that the "os" was not within reach. The cervix was enlarged, but little if at all more resistant than usual. On the finger being directed to the anterior wall of the vagina, a firm tumour was felt, evidently the body of the uterus much enlarged, which is pressing down on the lower part of the bladder, which of course left no doubt as to the nature of the case I had to deal with. The leucorrhœa at this time was trifling. On introducing the speculum I found the upper part of the vagina somewhat congested, also the cervix which was of a florid hue. There was no possibility of seeing the "os uteri," but the patient being on her back and the index finger of the left hand being introduced into the rectum, I was enabled to depress the cervix to such an extent, as to bring the edge of an ulcerated surface into view. The congested and heated condition of the cervix induced me to scarify it freely, which quickly did the office of many leeches without the tediousness of them. Two pills of extract of colocynth, and blue pill with extract of henbane, to be taken at once, to be followed by an enema. The recumbent position to be strictly adhered to.

16th. The bowels have been freely moved without effort to the patient; the calls to micturition, however, have been very frequent, but a difficulty almost amounting to complete obstruction exists within the last few hours; only a few drops passed at a time, and there being a considerable quantity in the bladder, it was drawn off by a catheter. The next day (17th) the same state of things existed; the urine had been drawn off three times altogether, and I determined to endeavour to rectify the position by manual interference, especially as my patient became feverish and extremely excited. Lying on her back, with the pelvis elevated, and thighs flexed, I introduced the fore-finger of the right hand up to the cervix, and with the left made firm pressure over the hypogastric region, and as it were, behind the pelvis. By this means the cervix was so depressed that the finger could be passed to the posterior aspect of it, and thus hooked, it was drawn downwards and forwards. This favourable position was not wholly maintained on the pressure being removed, I therefore applied a compress and bandage over the hypogastric region, as low as possible, which appeared beyond my expectation to second my efforts. On introducing the speculum to examine, if possible, the "os," and the whole of the ulceration, I was enabled so to do with the aid of the finger in the rectum. (I may remark this female's pelvis was very capacious, and vagina relaxed.) The ulceration I found chiefly on the anterior portion, extending to the edge of the os uteri, it was above the size of a shilling, and covered with small bleeding granulations.

Viewing in this ulceration the foundation of all the evil, I immediately commenced the treatment by freely applying nitrate of silver to the granulating surface, as likewise to the hypertrophied neck, and ordering an injection of diluted compound alum solution. The pills were requested to be taken every night, both as an alterative, and for the purpose of making defæcation *as easy* as possible, but above all, the recumbent position, and as much as possible on the back. The next day, after a tolerably easy night, I found the chief symptoms all better, with the exception of the leucorrhœa, which had increased, but which is usual, (I have found,) at first, after the application of the nitrate of silver. Micturition had been rather frequent, but without pain. The pills and injection to be continued.

On the fifth day I again examined with the speculum, and was able to get at the seat of mischief, without any aid through the rectum. The vesical symptoms had all subsided, but she still felt the bearing-down sensation on assuming the upright position. The cervix uteri still continues much larger than ordinary, but the ulcer is improved in appearance, and bleeds but little under the pressure of the speculum. The caustic was freely applied, and repeated every fifth or eighth day, for five weeks subsequently, when the ulceration had disappeared, and the healthy character of the cervix, as to size and colour, had been restored. The uterus had gradually returned to its normal position, which improvement took place progressively in keeping with the diminution in the consistency and size of the cervix. Her general health had improved, still she complained of weakness and deficient appetite, for which I prescribed iron and quinine, together with an occasional aperient of the compound rhubarb pill, with hyoscyamus. At the end of eight weeks there was continued improvement; the catamenia had returned, improved in quantity and quality, and without pain in its flow, which had been the case for months prior to treatment; all local irritability ceased, and the leucorrhœa had completely subsided. The cervix uteri, although probably more voluminous than usual, was soft, and its mucous membrane of its natural pale hue. The dyspeptic symptoms rapidly gave way, and she regained her former health and strength.

REMARKS.

The symptoms of anteversion, as I before remarked, are not always very prominent, providing the displacement has been gradual, but when it has taken place suddenly, as many cases recorded show, the general symptoms from the first moment are most severe and distressing. No age seems exempt from it, as it has been observed from the earliest to the latest periods of life. Pregnancy, in its first month or two, may prove a predisposing cause, acting in the same way as the congested and hypertrophied condition of the uterus, in the case before us, appears to have done. The after progress, then, of pregnancy, would in all probability act as its cure. Dr. Ashwell states that "the direct causes, those producing immediate displacement, are—falls, violent and sudden muscular efforts, straining at

motion, or in the evacuation of the bladder." From what I have been able to gather from the cases I have myself seen, as also from various published ones, it appears extremely doubtful if these direct causes ever act without the uterus is predisposed to such an accident, either from hypertrophy, (very rarely pregnancy) or a tubercular condition of the uterus, especially of its anterior wall. Tumours in the pelvis, posterior to the uterus, have been said to act as a direct cause, by pushing the fundus forwards. In the case above no cause could be traced other than congestion and hypertrophy, induced by ulceration of the uterine neck. The displacement appeared to have been so gradual that but little attention was aroused until it had become so complete as to interfere with the regular function of the bladder. Within the last four months I have been attending a lady in my neighbourhood with very severe ulceration, accompanied with great hypertrophy of the cervix uteri; it had evidently existed for more than a twelvemonth, occasioning three miscarriages, and at the time I first saw her the symptoms of early gradual displacement were exhibiting themselves. For the first month of treatment there was no possibility of examining the "os" through the speculum, but subsequently, on the ulceration and hypertrophy being partially cured, there existed no difficulty in ascertaining that the posterior aspect of the cervix was also ulcerated, though to a trivial extent compared with that on the anterior. The symptoms of irritability of the bladder had at this time also completely subsided. From increased experience of diseases of the uterus, and especially of simple ulceration inducing hypertrophy of that viscus, I am convinced that anteversion of the matrix, in a slight degree, is a far more frequent affection than is usually deemed, certainly according to my later experience, greatly more so than retroversion. I have frequently seen cases, such as that mentioned above of Mrs. S., where the early symptoms existed, and in which, had the congested hypertrophied condition of the uterus been allowed to go on untreated, I believe the same result would have been brought about as was seen in Martha E., at all events, had any exciting cause brought it into action, such as a fall, violent sickness, &c., &c. This brings to my recollection the case of a patient (the Hon. Mrs. M.,) whom I attended last year with ulceration and a hypertrophied condition of the womb, which had existed for four years. This lady suffered for many months from all the chief symptoms of anteversion, in a slight degree, (especially the urinary,) after any unusual exertion, either in travelling or dancing, which compelled her to keep the recumbent posture for at least two days after. On two of these occasions (the result of her imprudence,) I had the opportunity, by examination, of verifying the cause of those unpleasant symptoms to be slight displacement. The presumptive symptoms of anteversion of the womb are very similar

to those seen in the more severe cases of simple ulceration, with the exception of irritability of the bladder and rectum, and difficulty of micturition and defæcation, although undoubted cases of anteversion of a complete character have occurred, without either of these symptoms having existed. These presumptive symptoms,—*e. g.*, dull, aching, lumbar pain, "bearing down" pain in the upper hypogastric region shooting down the thighs, leucorrhœa, &c., imperatively demand an examination per vaginam, both by the "toucher" and speculum, and not a blind resort to astringent injections for the relief of leucorrhœa, which, in the majority of cases, is a mere symptom of a worse evil, and which, if allowed to go on, may induce obstinate hypertrophy and displacements in its train, as the above cases show. With respect to the *diagnosis* of anteversion, very little difficulty I conceive exists, after a careful examination per vaginam. The cervix will be found high, sometimes with difficulty reached; the extremity or "os" will be pointed towards the sacrum, and applied against it. An examination by the rectum will make this evident, if the situation of the cervix is too high to be clearly made out by the vagina. In the anterior wall of the vagina, a tumour or prominence will be detected pressing against the lower part of the bladder, which, on accurate investigation, may be traced to be continuous with the cervix, in fact, the fundus uteri. This tumour anteriorly may be felt very readily by passing a bougie into the bladder. It is scarcely possible to conceive how such a prominence in the bladder could be mistaken for a stone in that viscus, but such has been the case, and the operation performed for its removal, the death of the patient alone having revealed the *true* nature of the malady. Such sad experience teaches a useful lesson as to hasty and erroneous diagnosis, such as is too often made; it is to be feared that practitioners are too frequently apt to neglect the education of the organ of perception—a faculty of the mind perhaps the most useful to the physician and surgeon, and one, the eager cultivation of which the student at the bed-side should keep constantly in view, in order that clinical experience may turn to usefulness and success in practice. The symptoms I have called presumptive will lend their aid, but the diagnosis can scarcely be difficult with the physical symptoms known. From retroversion, anteflexion, and other displacements, as also from pelvic and other tumours, anteversion can scarcely be confounded after a careful examination.

The *treatment* of cases of the slighter kind require but little for their rectification other than the recumbent position, (which is a *sine quâ non* in all cases,) and the rectum kept empty by means of mild aperients and enemata; should much local or general irritability exist, an anodyne of henbane or morphia will be of service. The predisposing cause should, however, always be held in view. If inflammatory congestion

exist, antiphlogistic treatment, leeches or scarifications, with salines and alterative doses of mercury, will be found useful. If there be simple ulceration, with induration and hypertrophy of the cervix, subsequent appropriate treatment should be put in force, by caustics and astringent injections, especially of zinc, alum, or tannin; the latter, when applied by means of a sponge or large camel's hair pencil, through the speculum in a concentrated solution, to the ulcer after it has been brought to a healthy condition by lunar caustic, I have seen very rapidly to cause it to cicatrize. In the severer cases, however, if the milder treatment be of no avail, and the pain and difficulty of micturition be great, requiring the constant aid of the catheter, an attempt to restore the structure of parts should be made. The rectum having been emptied of its contents by an enema, the patient placed on her back, with her thighs flexed and pelvis elevated, one or two fingers of the right hand should be introduced, and an attempt made to *hook* the index round the cervix, at the same time pressure must be made upon the fundus, which will facilitate the object; gentle traction should then be made upon the cervix, and the depression will, in all probability, be easy; if, however, the cervix cannot be thus reached, an instrument similar to the one invented by Madame Boivin may be employed, but will require caution. With regard to pessaries, I say nothing in reference to their use in preventing a recurrence of anteversion, as I cannot conceive of their capability of being, in the slightest degree, serviceable. After the parts have regained their normal structure and position, mineral tonic remedies, with astringent injections, cold hip-baths, or sea bathing, (where the powers of the patient will permit,) will more completely answer this end, by giving tone to the system, and thereby overcoming a relaxation of the contiguous parts, which always, in a greater or less degree, precedes the accident.

CANCER OF THE UTERUS, BLADDER, &c.: CASE AND REMARKS

By EDWARD BALLARD, M.D., Leamington,

Late Senior Physician to the St. Pancras Royal General Dispensary, and Medical Tutor in University College, London.

The last case which I recorded was one in which the cancer not only affected the body of the uterus, but this alone. That which I am now about to relate illustrates the more ordinary form of the disease,—namely, when it first attacks the cervix, and in which its ravages are chiefly carried on in this portion of the

organ. I have selected this case, although I had no opportunity of seeing the termination, because it exhibits the most important and characteristic features of the affection, and also some interesting complications.

CASE.

Miscarriages, &c.; Menorrhagia; Vaginal Discharge; Lacerating Pain; difficult Defecation; Ulceration of Cervix Uteri; Hematuria and disordered Micturition; Cancer of Bladder; Edema of Leg; Ascites, &c.

S. H., aged 33 years, residing in an unhealthy street in St. Pancras parish, placed herself under my care at the St. Pancras Dispensary, on September 1st, 1846. She had a fine fair skin, and dark fine hair. No hereditary taint. Has not undergone any considerable amount of privation, but has been often without sufficient clothing in the winter. The catamenia commenced at twelve years of age; the discharge used always to be abundant, and she used to suffer much pain in the back; it was not clotted. Her courses never recurred regularly, but at intervals, varying from three to thirteen months, *except when suckling the first four of her children*, when they occurred at intervals of three weeks, lasting from five to nine days; they occasionally appeared also while she was nursing her other children. She menstruated once when pregnant with twins. She married at the age of seventeen years, and her first child was born eleven months afterwards. She had four more within the next seven years, and then for the first time suffered a miscarriage at nine weeks, but at that time lost but little blood. The next year she was confined with twins, and subsequently had two other children, her last labour occurring in July, 1844. This last child lived but a few minutes after his birth. To the particulars of this pregnancy and labour I shall again recur.

On enquiring into her previous history, she stated that she had always been "very nervous," and although never subject to fits, the physicians who saw her at St. Bartholomew's Hospital regarded her as hysterical. It appears that when a child she received a severe burn over the right shoulder and arm. So long as she could recollect, her bowels have been habitually much relaxed, and she has been subject to pains under the left breast, shooting through to the left scapula. She has often been subject to passing "red sand," and also to difficult micturition. This symptom has not appeared so frequently of late, although with the progress of her disease the difficulty of micturition increased.

About two years ago, when two months advanced in her last pregnancy, she began to suffer from a discharge of blood, accompanied by bearing down pains, like labour pains. This continued throughout the pregnancy, but became much more serious during the three last months of it. She was attended in her confinement by a midwife, and in consequence of improper manipulation, as it is supposed, the neck of the uterus became torn. This is the report of the medical gentleman who was subsequently called in.

He stated to me that he believed there was a partial placental presentation. He thought that the tearing of the cervix might have been due to the presence of commencing malignant disease. After her labours she was attacked with "inflammation of the womb," for which she was leeches and blistered. In eight or nine days she stated that "an abscess formed and broke, discharging a quantity of foetid, yellow, and watery matter," and caustic used to be applied through the speculum. Since this period she has never been free from a vaginal discharge, and has not menstruated with regularity. She miscarried twice in the autumn of last year, and at the close of it, entered St. Bartholomew's Hospital, where she was said to be labouring under "disease of the womb." Last January, after she left the hospital, she was seized suddenly one night with flooding, and this continued more or less till March. It was followed by a vaginal discharge, which, however, did not assume the cancerous odour till two months ago. Shortly before the flooding she began to experience a difficulty in passing her stools. About February, her complexion was first noticed to become sallow, accompanying pallidity, from the loss of blood. Six months ago there was a temporary swelling of the left leg and thigh.

She is now moderately emaciated; her countenance pale, waxy, and sallow. For the last three months she has complained of an aching gnawing pain above the crest of the left ileum, extending to the groin, and during the last two months, to the inner side of the thigh and knee, accompanied with tenderness; and there are some swellings in the groin. Almost ever since her last labour she has suffered from shooting pains from the vulva through the pelvis to the lower part of the back, so severe as to cause her to start up if she be sitting or lying. There have been also aching, shooting, and bearing down pains about the lower part of the abdomen. The lancinating pelvic pains have been much more severe of late. She spends the greater part of the day in bed because her back is then easier, and sitting induces the pain in the groin. She has been taking opium in quantities of three or four grains daily, for the last six months. Her appetite has fallen off; but she suffers from thirst. There are pains around the navel, with borborygmi, and occasionally under the left breast, and there is tenderness at the bottom of the belly and over all the left side of the abdomen. She frequently vomits in the morning. Bowels have been constive ever since her labour; the stools are hard and lumpy, passed with difficulty and pain. There is much difficulty in micturition, and the urine is scanty—sometimes not more than a tea-cupful in a day. The vaginal discharge is abundant; not mucous, but watery, and of a reddish colour. It has a most powerful cancerous odour, perceptible on entering the room. Once or twice two or three "hard lumps" have come away. *Vaginal examination* painful. Cervix uteri completely destroyed, its base being occupied by an ulcerated cavity of about the size of a half-crown piece, with a hard thickened border. A portion of a hard tumour was felt lying against the left side of the rectum, and a largish hard tumour met the finger on pressing upwards and forwards at the lower

part of the vagina. She has found her pains greatly relieved by using a hip-bath as hot as she can bear it, and asked permission to continue it. She was ordered in addition two grains of opium with some soap as a suppository at night, and an occasional dose of castor oil. Two days after, suddenly applied pressure detected a solid organ, probably the uterus, extending two inches above the pubes.

The opium relieved the lancinating pains, but she once or twice suffered from diarrhœa for a day or so. This occurred on September 11th and 12th, on the former of which days she passed no urine, but on the latter hæmaturia appeared, accompanied by a return of the lancinating pain and increased difficulty of micturition. On the 13th it had much abated, and on the 15th the urine contained no blood. The blood appeared in clots at the bottom of the vessel. Still, however, after having emptied her bladder, she felt a desire to pass more urine. The diarrhœa returned on the night of the 15th, and the hæmaturia on the 17th; they appeared to alternate. On the 18th, the urine presented soft deep black clots at the bottom of the vessel. The flow of urine frequently stopped suddenly with very severe pain, and after it ceased she suffered much aching pain in the perineum. The vaginal discharge was unaltered in character. On pressing the abdomen there was much muscular resistance perceived on the left, but not on the right side. On the 19th the urine was less bloody; but a smooth uniform reddish deposit was present, consisting of blood, mucus, and pus corpuscles; its specific gravity was 1.010, and when boiled, the albumen occupied one-eighth of its bulk.

September 24th. No hæmaturia since the 19th, and she has been freer from pain than for some days previously. The urine remains very scanty, and is passed with difficulty. She has now no gripping pain around the navel, but little pain in the groin, &c., and no lancinating pain. A new appearance however is presented: the belly is fuller, but very yielding, except on the left side. There is some enlargement of the superficial veins at its lower part, especially on the right side. There is slight dulness above the pubes where there has hitherto been resonance, but no fluctuation can be detected. The urine examined on the 25th still contained a little blood. From this time the appetite improved, although she suffered somewhat from thirst, and she passed her urine more freely and more abundantly.

October 8th. On the 4th, the left leg was observed to be swollen. The swelling commenced in the groin and proceeded downwards, and now occupies the entire limb; it is greater when she sits up than while in bed. There is also aching pain in the back part of the thigh and calf. The superficial inguinal glands on the left side are enlarged and tender, but not fixed. No red lines proceeding from them, and no apparent thickening of the veins or lymphatics of the limb. On the right side, the glands are less enlarged; there is no swelling, but some small knotty veins are felt passing over Poupart's ligament, and ending opposite the saphenous opening. The urine examined on the 9th presented no blood, but a deposit consisting of pus

globules. On the 11th, the swelling of the left leg began to diminish, but that of the abdomen to increase. When visited on the 16th, she complained of general aching pains in the belly, especially on the left side, and also of a sense of tenderness on pressure above the navel, in both flanks and iliac regions, and in the left hypocondrium. She stated that ever since the hæmaturia ceased her urine had been flowing from her involuntarily, but that sometimes she could pass a little with straining, but only in drops. The vaginal discharge had lessened and become less offensive. Fluid detected in peritoneum in small quantities by dulness on percussion, and fluctuation in depending parts. The latter was difficult to ascertain, and easily destroyed by pressure. Under the use of half an ounce of cream of tartar, with a few grains of ginger every morning, this was beginning to lessen, when I was refused any further attendance on her from her husband's objecting to physical examination of the abdomen.

REMARKS.

It is doubtful at what time the uterine cancer in this case began to be developed. There is never any difficulty in recognizing it when advanced to the extent that was observed when this patient first came under my notice, but it is often not so easy to determine either from the history or from the condition of the organ, how long it may have existed. Of one thing we may be certain, however, in the instance before us, namely, that eight months before the patient presented herself at the Dispensary, the disease was not only present but advanced, since at that time she underwent one of those sudden and characteristic attacks of menorrhagia, which are so common in the course of uterine cancer that in twenty-one cases observed by Louis, only one went through its course without it.—(*Walshe on Cancer.*) I say that at that time the disease was advanced, and I judge it to have been so from the occurrence previously of difficulty in the act of defæcation, which I found was attributable to the pressure of a *secondary* cancerous growth upon the rectum. In by far the majority of instances of cancer of the womb, hæmorrhage is the first symptom which attracts attention to the organ, so insidious is the approach, and so undecided are the indications to the patient of the earlier stages of a disorder, second to none in fatality, or in the distress which accompanies its complete development. In this case, however, there had been symptoms pointing to the womb as the seat of disease, although the history does not indicate that they were distinctive of malignancy. She had suffered twice in succession within a few months from abortion, during the autumn preceding the hæmorrhage, and just prior to the latter, had been discharged from one of the London Hospitals, where she had been recognized as labouring under uterine disease. To look back still further, the earliest symptoms of any disorder of the womb manifested themselves subsequently to a labour

in which there was a partial attachment of the placenta to the os uteri, and during which the cervix had become lacerated. There continued such disease in the cervix as to demand the frequent use of cauterization. A point of interest connected with the flooding is, that the patient was not one in whom the catamenial functions were performed with any regularity, except during the sympathetic irritation which suckling gave rise to. The sudden hæmorrhage thus was the more remarkable, and the more indicative of serious disease, that it was the very opposite condition to that which was established as the habit of her system. The remaining *symptoms* of the disease were lancinating pain, vaginal discharge, sallowness of complexion, and sympathetic disorder of the stomach. The lancinating pain was perhaps not entirely due to the uterine disease, but partly to that conjoined with it in the bladder, since it was increased in severity when the other symptoms of the latter affection became more marked. The discharge at the time I saw the patient was reddish and watery, the appearance usually presented when the cancer is advanced to the stage of ulceration. It presented also that remarkable odour which requires only to be once smelt to be recollected for a life time. The result of digital examination left no doubt as to the disease under which she laboured.

In connection with the causes of the disease, we must be struck with the early age at which the catamenial discharge first appeared, with the early age at which the woman married, and the number of times she had conceived. Had these circumstances anything to do with the tendency to the affection? The case last related occurred, too, in a prostitute. Statistical enquiry has decided in the negative, and has confirmed the opinion which the experience of those who have seen most of the disease had led them to form,—namely, that sexual regularities or irregularities, frequent or unfrequent pregnancies, temperate or intemperate intercourse, numerous miscarriages, or the reverse, have nothing whatever to do with the development of the disease.

I have already alluded to hypertrophy of the uterus as a complication of cancer. In the last case it was very extensive, but here was moderate, the difference probably depending on the difference of seat in the primary disease.

Cancer of the Bladder.—Although we cannot on good evidence deny the occurrence of cancer of the bladder as a primary affection, yet it is far more common secondarily to that of other parts, and especially to cancer of the womb. It was indicated in this case both by symptoms referable to the bladder and by physical evidence in addition. The latter was the perception of a tumour in the situation of the base of the bladder, of whose nature there could be little question when it was considered in what connection it

was found. One of the most remarkable of the symptoms was the *hæmaturia*. This was evidently of vesical origin, no sign of renal disease having preceded or followed it, while it was accompanied and succeeded by other signs of irritation in the bladder. It was, in addition, sudden and severe; and there was no exciting cause distinguishable. These are just the characters which mark hæmorrhage from cancer of the bladder. The urine, however, though carefully and repeatedly examined, afforded to the microscope no appearances which would tend to have confirmed the diagnosis, no cancer cells being perceptible, and the deposits presenting only the products of hæmorrhage and of inflammation of the mucous membrane. Another symptom of the disease was the difficult micturition, due perhaps to the position of the cancerous growth and the sense of dissatisfaction which followed the completion of the act, the belief of the patient being that something yet remained in the bladder to be discharged. I need merely allude to the alternation between the uterine hæmorrhage and the diarrhœa as a matter of interest. Of all the seats of vesical cancer the base of the organ is the most ordinary part to be affected. In this point, therefore, the case before us presented nothing peculiar, but it was remarkable in the independence of the deposit of contamination by mere contact with the uterus. For the most part it is thus that the bladder becomes affected, the disease spreading from the cervix uteri to the organs and tissues in its neighbourhood, but here the deposit in the bladder was perfectly isolated, having no connection whatever with the seat of primary disease.

Cancer of the Lymphatic Glands within the Pelvis is a complication of uterine cancer by no means rare. In the present case there was no physical evidence of it in any but one situation,—namely, as constituting the tumour felt in the vaginal examination to be pressing against the left side of the rectum. It is highly probable, however, that this was merely a part of a more extensive implication of the lymphatic system in the pelvis, if we may judge by a variety of symptoms which this, conjoined with intercurrent attacks of inflammation, will suffice to explain. I refer, of course, to the symptoms localised in the neighbourhood of the groins, of the hip, thigh, and leg, especially of the left side. The pressure exerted by these glands on the branches of the anterior crural nerve and on the sciatic, will account for the pain she experienced in these situations, for the obstruction to the return of blood, as pointed out by the enlargement of the veins, while the temporary œdema of the leg may be explained by an increase of their bulk and pressure under the influence of inflammatory turgescence. The character of the swelling, too, was remarkable; it did not commence with the ankle and extend upwards to the thigh, but on the contrary, began in the groin, and spread downwards to the leg.

This puts one in mind of *phlegmatia dolens*, in which the swelling usually follows this order, and its pathology presented nothing very different from that complaint. It differed in the swelling, being distinctly influenced by changes in the position of the limb. Must not the *ascites* which had followed on the lessening of the swelling of the leg be attributed to the influence of the same local cause? Most of the cases of *ascites* we meet with in practice are due to obstruction in the venous circulation of the abdomen; but there is also an inflammatory *ascites*, the result, not only of general contamination of the blood with non-excreted matters, as in renal disease, but also arising from a more local cause of irritation. This was probably the case in the present instance.

I must allude, before closing these few pathological observations, to the resistance offered by the abdominal muscles to the hand over the left side of the abdomen; in fact, where it would have excited pressure indirectly upon the diseased organs. It is a sign never to be neglected in the determination of abdominal disease, and when presented by one part more than by another, it is a pretty certain token of disease in its neighbourhood, even when no complaint of tenderness is made by the patient.

Leamington, April 4, 1849.

TOTAL SUPPRESSION OF URINE DURING SEVEN DAYS,

TERMINATING IN RECOVERY.

By W. S. OKE, M.D., Physician to the Royal South Hants Infirmary.

Dr. Watson, in his admirable "Lectures on the Principles and Practice of Physic," states (Lecture 77,) that "this affection usually occurs in persons who are advanced in life, and inclined to corpulency." He also writes as follows:—"Sir Henry Hallford has related one of five instances of this disease that he had met with in the course of twenty-seven years; he says it was an exact copy of all the others that had fallen under his notice. As his account of the general course of the symptoms coincides with the statements of other writers, I may give you his narrative in lieu of a formal description."

"A very corpulent robust farmer, of about 55 years of age, was seized with a rigor, which induced him to send for his apothecary. He had not made water it appeared for twenty-four hours; but there was no pain, no sense of weight in the loins, no distension in any part of the abdomen, and therefore no alarm was taken till the following morning, when it was thought proper to ascertain whether there was any water in the bladder, by the introduction of a catheter, and none was found. I was then called, (says Sir Henry,) and another inquiry was made some few hours afterwards, by one of the most experienced surgeons in London, whether the bladder contained any urine or not, when

it appeared clear that there was none. The patient sat up in bed, and conversed as usual, complaining of some nausea, but of nothing material in his own view, and I remember that his friends expressed their surprise that so much importance should be attached to so little apparent illness. The patient's pulse was somewhat slower than usual; and sometimes he was heavy and oppressed. I ventured to state, (continues the author,) that if we should not succeed in making the kidneys act, the patient would soon become comatose, and would probably die the following night, for this was the course of the malady in every other instance I had seen. It happened so, he died in thirty hours after this in a state of stupefaction."

I have deemed it right to quote this case in detail, representing as it does the five fatal instances met with by the late Sir Henry Hallford, in order that the case about to be related may be compared with it, and to show that the constitution might sometimes tolerate excrementitious poison in the circulation for a much longer time, and even recover from its baneful effects.

A gentleman, 75 years of age, of short stature and spare habit of body, had, in the earlier part of his life, suffered severely at times from disordered function of the urinary organs, but for many years past he had enjoyed an exemption from his complaint by observing a more abstemious diet, and by taking alkalines, at the recommendation of an eminent London surgeon. Supposing that he had completely got rid of his complaint by this treatment, he ventured to return to his former habit of incautious living. The result was, that he became again subject to the same symptoms, and in one of these attacks, at the latter end of October last, he was attended by his medical friend, Mr. John Rushworth Keele, an experienced surgeon of this town. The symptoms became alarming, and as a total suppression of urine had taken place, I was requested by Mr. Keele to meet him in consultation on the 31st of October. It appeared that the attack was preceded by rigors, which were followed by symptoms of renal obstruction; that the warm bath, with other suitable means, had been tried; and that a common-sized catheter had been judiciously introduced, to ascertain whether any urine was retained in the bladder, but no urine was found.

When we saw the patient in consultation the following facts were noticed:—No urine had passed since the 30th; there was no distention of the pubic region; and upon another cautious and facile introduction of the catheter by Mr. Keele, the bladder was found quite empty; there was no pain nor uneasiness of the loins, along the ureters, or in the course of the spermatic nerves; neither was there any contraction of the cremaster muscles; but there was a more frequent desire to make water than is natural, and so extremely urgent was the call, that he required the vessel to be handed instantly, "lest (according to his words,) the urine should flow over the bed." Each effort was exceedingly straining and painful, as in dysuria, and caused him to cry out loudly, but the only result of his efforts was a few drops of bright blood. The system was but little disturbed; the tongue moist, and not much furred; the pulse about 90 in the minute,

and regular; the skin cool; and what was very remarkable, although he had been a person of a very irritable temper, he had now become subdued, placid, and composed.

Supposing from the patient's advanced age, that the suppression may be caused by atonicity or degeneration of the structure of the kidneys, we decided on first trying the effect of stimulant diuretics.

R. Olei Terebinthinæ purificati, guttas xv.; Tinctr. Hyosciami, m. xxv.; Aquæ Cinnamoni, oz. j. Misturæ Acaciæ, q. s., adbene miscend. Capiat hanc dosin quarta quaque hora. Fricetur subinde in lumborum regionem Linimentum Terebinthinæ.

At an evening visit, finding that there had been no action of the kidneys, the following was ordered with a repetition of the warm bath.

R. Pulveris Ipecacuanhæ Compositi, gr. iv.; Nitratis Potassæ, gr. x.; Misturæ Acaciæ, Syrupi Simplicis singulor, dr. j. Misturæ Camphoræ, oz. j. Misce pro haustu quartis horis sumendo. Capiat cras mane Olei Ricini, oz. ss.

November 1st. He has passed a tranquil night, with snatches of sleep; the bowels have been moderately acted upon; the same strainings of the bladder continue; but there has been no secretion of urine. He has been sick and has vomited.

Sumat haustum sequentem inter effervescentiam, quarta quaque hora cum granis quindecim Acidi Citrici in Aqua pauxillo diluti.

R. Sodæ Sesqui-Carbonatis, scr. j.; Liquoris Opii Sedativi Min. quinque; Spiritus Ætheris Nitrici, m. xx.; Syrupi Simplicis, dr. j.; Aquæ Destillatæ, oz. j. Misce

Vespere. He is much the same in every respect; no urine has passed. Repetatur balneum tepidum et pergat iisden medicamentis. Repetatur Olei Ricini, oz. ss., primo mane.

November 2nd. The vomiting continues, and there is the same ineffectual straining to make water, voiding only a few drops of blood. Between these distressing efforts he lies down in his bed calm and composed. The tongue is somewhat furred, and the pulse between 80 and 90 in the minute. The bowels have not responded to the castor oil. Applicentur cucurbitulæ cruentæ regioni lumbali, et injiciatur per anum enema purgans.

He was also directed to take a dose of some aperient pills, to which he had been accustomed, if the bowels should require them.

3rd. The strangury, suppression, vomiting and constipation continue as yesterday. He remains composed in the intervals of endeavouring to pass water, but there is no tendency to coma. Repetantur balneum tepidum, enema purgans, et pilulæ aperientes.

4th. The symptoms continue with but little variation; the stomach resists everything, and he is evidently weaker; not a drop of urine has been passed. The catheter is once more easily and cautiously introduced for the satisfaction of his relations; but no urine whatever was found in the bladder, and no blood followed its withdrawal.

During the 5th and 6th, he went from bad to worse. The matter evacuated by the stomach became dark and fetid; an urinous smell was perceptible in the

breath; the pulse fell; the temperature of the extremities was diminished; and his mind wandered.

On the evening of the 6th, there was no improvement in any respect; and he appeared fast approaching the moribund state.

On the morning of the 7th, I called as I supposed for the last time. Finding my colleague and one of the patient's sons with unusually cheerful faces, and enquiring the reason, I was requested to go up-stairs and satisfy myself. There, to my great astonishment, I saw that the patient had during the night passed an ordinary chamber-vessel nearly full of urine, somewhat tinged with blood; and I soon found, that instead of the subdued and placid manner exhibited during the whole time of the suppression, his natural irritability of temper had returned; for upon congratulating him upon so great a change for the best, he sharply and pettishly exclaimed,—“Better, Sir, Better! how can that be possible, when it must be evident that I am sinking into the grave every moment!”

In this, however, he was mistaken, as the kidneys continued to act, the vomiting subsided, the bowels resumed their functions, and under the care and attention of Mr. Keele, he gradually recovered as good a state of health as so formidable a malady at his advanced age could allow us to expect.

He still occasionally suffers from dysuria; but there has been no return of the ischuria renalis, although it is probable the latter might again take place.

I shall not go into the question of the proximate cause of the renal obstruction, as such an enquiry would be merely hypothetical and inconclusive; neither shall I allude to the treatment as having been successful, as the removal of the suppression cannot fairly be attributed to any of the means employed. I have stated the case (very briefly) to shew that we are not always to despair of recovery where the suppression of the urinary secretion is total, and where the cerebral functions might be exposed to the full action of an excrementitious poison during seven days. If the suppression had not been complete,—even if a few ounces of urine had been secreted in the seven days, I should not have deemed the case worthy of being recorded. Doubtless many of my professional brethren could adduce instances of urinary suppression, and perhaps with the like result; nevertheless, I believe such instances to be of uncommon occurrence.

It is singular that under circumstances so favourable to its production there should have been no comatose condition of the brain, for, although the mind occasionally wandered on the sixth and seventh day of the ischuria, there certainly was no coma; it is, however, probable, that the subdued and composed state of the nervous system was the incipient sedative effect of the urinous poison circulating in the blood, and that, had it been longer retained, a fatal coma would have been the result. This opinion is strengthened by the fact, that with the restoration of the renal function, the composed state of the patient was at an end, and all his former moral irritability returned.

Southampton, February 22, 1849.

ON ABSCESES OF THE PELVIS UNCONNECTED WITH PARTURITION.

By JOHN S. BARTRUM, F.R.C.S., Surgeon to the
Eastern Dispensary, Bath.

(Read at the Quarterly Meeting of the Bath and Bristol
Branch Association, March 22, 1849.)

The cases to which I wish to draw attention are—pelvic abscesses, not connected with parturition, which, not being of every-day occurrence, nor, on the other hand, presenting any very marked peculiarities, are yet of sufficient importance to receive special notice, particularly as they often cause the patient prolonged anxiety, and in their earlier stages present difficulties in diagnosis which the issue of the cases only solves. Moreover, they well illustrate how much the powers of nature will effect towards cure without receiving any more surgical aid (though that, indeed, is much) than is derived from general and constitutional remedies, without any treatment being applied to the parts at first attacked.

My attention was first drawn to diseases of this class in 1838, while acting as clinical clerk to Dr. Watson, at the Middlesex Hospital, when two cases of inflammation of the pelvic peritoneum came under my observation. Not being under the care of Dr. Watson, I did not take notes of them, but well remember that in one case there was found a large accumulation of purulent matter in the pelvis, while the abdominal peritoneum was unaffected. The other case, I believe, recovered.

CASE I.

The case which first came under my own care and notice was in a lady, single, aged about 30, of the most active temperate habits, who for two or three months had suffered from depression, languor, and a dull pain in the head and loins.

On March 30, 1842, she was attacked with pain in the bowels and groin, with a feeling of weight in the right lumbar region, extending to the pubes, which being accompanied by sickness, and the excretion of gravel was ascribed to the passage of the gravel down the ureter. On the second day there was tenderness and obvious fulness in the right iliac and hypogastric regions; the spinal column was nowhere tender. There was at first some sense of prolapsus, and continued pain in passing a motion, and bearing down in the rectum. Prior to this attack, and at each recurrence of the subsequent minor attacks, there was pain in the bladder, and partial stoppage of the urine. She continued in a weak feverish condition for a fortnight, when, while sitting at table, there escaped from the vagina a large quantity of offensive purulent matter, mixed with flakes of lymph; this discharge continued for several weeks. She had not suffered from habitual constipation. In this convalescent state she came under my care, still complaining of pain in the right iliac and inguinal regions, the

discharge being much less, and her other symptoms much improving.

After several slight subsequent attacks, she wholly recovered her health, and is now quite strong and vigorous. The treatment consisted of warm baths, opiates, effervescent salines, and absolute rest.

CASE II.

This case is one of very simple character, it having arisen from exposure to cold, and was not seated deeply within the pelvis.

November, 1845. E. D., aged 32, married, but never pregnant, having wetted her feet shortly after menstruation, was attacked with shivering and feverishness, and after some days was unable to sit down, or to pass her motions without much discomfort; her bladder was not affected. When called to her a fortnight after the preceding symptoms had first been felt, I found on examination, a large soft swelling high up, and on the left side of the vagina, between it and the rectum. In the course of ten days the swelling much increased, and when opened, a large quantity of healthy pus was let out. The patient shortly recovered, and has not felt any further inconvenience than some pain in the same region on every change of weather.

CASE III.

This case in its early stage appeared more complex, the collection of pus having caused complete retroversion of the uterus; her recovery was, however, complete and rapid.

E. F., aged 30, mother of three children, and suckling one six months old. Her labour had been perfectly natural, since when, till two months ago, she had nothing to complain of. About that time she began to find some difficulty in making water; she had no pain in the groin or abdomen, but had suffered much from a heavy pain across the sacrum.

October 20th, 1845. She applied to me on account of the utter inability to relieve her bladder. She had not passed any urine for thirty-six hours, and was necessarily much distressed. On passing the flexible catheter, the existence of some impediment external to the urethra was ascertained, and on examination I found the uterus completely retroverted, its fundus being thrown back on the rectum, while the cervix pressed on the urethra. For three days I used the catheter, and acted gently on the bowels by castor oil, intending to replace the womb, when, to my surprise, I learnt that on the fourth morning a large quantity of pus had been voided by the rectum, and found that the uterus had resumed its natural position. Her recovery was rapid. She has since had two children, without any further inconvenience.

CASE IV.

This case is one which, in its early stages, was very severe, and its diagnosis quite obscure.

A. H., aged 27, married; two children, youngest a year and ten months old.

July, 1845. Complained of pain and irritation in the rectum, simulating piles. The pain and difficulty in defæcation increased, and was not relieved by

laxatives or enemas; there was also a discharge of "whites," with much pain on connubial intercourse.

September 1st. Had an attack of shivering, with headache; bowels confined, but when they were acted on there was severe pain in the lower part of the abdomen. The next day, without any sufficient reason, they became excessively relaxed,—so much so that on the slightest exertion some fæcal matter passed away. In this state she continued for several days, the pain being increased by taking liquids.

4th. There had set in unequivocal symptoms of acute inflammation of the lower part of the abdomen; she was very tender in each groin, and below the navel, not being able to bear the weight of the clothes; there was no vomiting; pulse very small. The amount of pain, tension, and tenderness, varied for several days, but she gradually improved under active treatment. The result was, that after some days there was found, in the right inguinal and iliac regions, a large lump, extending from the crest of the ilium to the groin. This lasted for about a fortnight.

20th. As she sat up in bed, an urgent desire to relieve herself came on, when she voided from the rectum a large quantity of purulent matter, the inguinal tumour at the same time subsiding and becoming less tender. After the lapse of some days there was no trace of the swelling; there was no further discharge of pus. The leucorrhœa and feeling of prolapsus, with difficult micturition, also gradually passed off.

April, 1847. She had a slight return of pain in the sacrum, which one cupping, with the hot hip-bath, removed; since then she had neither piles nor prolapsus uteri; has not been pregnant till recently, being now (March, 1849) just out of her confinement with a fine healthy child. The labour had no peculiarities. The treatment during her illness was vigorous; she was twice bled; leeches were applied several times; blue pill and opium were administered, and poultices applied to the hypogastrium.

CASE V.

The case I am about to relate is much more chronic in its present stage, but at an earlier period probably presented features of acute activity somewhat similar to the last.

A. F., aged 35, has had two children, the youngest twelve years old, since the birth of which she has not been pregnant.

July, 1848. She states that seven years ago she had inflammation of the bladder, with excessive pain in the hypogastrium, and continual desire to micturate, which gave her much pain. For this she was admitted into the Bristol Infirmary, where she was for some weeks, and was freely leeches, she then requiring the use of the catheter. Since she recovered from that attack she had perfect power over her bladder, and has been able to attend to her usual domestic duties, and has not suffered from menorrhagia.

Ten weeks ago, after having been wetted in the feet and legs while carrying a child, she suddenly found a thick, yellowish, white, (apparently purulent,) discharge from the vagina, accompanied by a sense of prolapsus.

Three days afterwards, at her proper time, menstruation began, and continued for ten days. From that time she has never been free of discharge to a greater or less extent; when the discharge is not coloured, it is thick, yellow, with a constant feeling of bearing down, and desire to micturate, which feelings are much increased by walking or standing. If she is not able to relieve her bladder, it causes additional suffering; the passing the water gives rise to a cutting pain. The urine is said to have been high coloured, with a thick sediment; the bowels have been confined. She states that before and after each motion she suffers much pain, with a sense of scalding and cutting up the sacrum. The motions are reported to be streaked with blood and matter. She is never free from pain across the sacrum and hips, especially on the right side. Deep in the right iliac and hypogastric region she is very tender, and that part is fuller than on the opposite side, though no circumscribed tumour can be felt.

On examination, neither the vulva nor cervix uteri were found tender, nor the vagina, except at the upper part of the recto-vaginal septum, which at one part feels fuller and bulging, and is quite tender. The os uteri feels natural; the uterus is not enlarged, nor tender, and is quite moveable.

March, 1849. During the last six months her state has varied, though on the whole she has materially improved; indeed she has now regained the hue of health, and is able again to attend to her family duties. She has had several minor attacks, attended by throbbing in the vagina, slight shivering, and flushes of heat. On one occasion (December, 1848,) she suffered from sharp pains in the groin, after which there was an abundant thick yellow discharge from the vagina, with much relief to the groin, the feeling being described as if something had given way. Not long afterwards, when the discharge had nearly ceased for some time, on passing a motion, there was a sharp pain on the right side of the sacrum, the motions being very dark and mingled with white matter; micturition was difficult, as though there was something in the way, with pain over the pubes. Passing the catheter gave her much pain.

The treatment has consisted of very gentle mercurials, combined with tonics; the sixteenth of a grain of oxymuriate of mercury, in tincture of cinchona, twice a day, by which her gums were slightly affected, and were kept just tender for some time, with marked benefit. This was followed by three-grain doses of iodide of potassium twice a day. Local counter-irritation was an important part of the treatment; blisters applied over the inguinal region gave very great relief. There is every probability of her now getting quite well.

The question that naturally arises from the consideration of such cases as these is,—what is the original disease? To me they appear to have been phlegmonous abscesses in the cellular substance of the pelvis, internal, in all the cases, to the pelvic fascia, for neither in these, nor in any of the subsequent ones (unless connected with cancerous degeneration, which will eat its way through any tissue,) was there a trace of irritation of the nerves of the lower extremity. What they most resemble are the cases of abscess

connected with the cæcal appendix; from this disease they differ in the inflammatory action being more deeply seated, and their affecting the pelvic viscera only, the bowels appearing to have been affected only secondarily, when the abscesses burst into the rectum, which consequently became excoriated. In neither of them was there any symptom leading to the belief that the bones of the pelvis were implicated, nor did they arise from the excitement of parturition, but, probably, from the high vascularity and excitable character of the pelvic viscera in the female, especially during the period of menstruation, when the exposure of the feet or legs to wet or cold will readily excite disorder.

In men the same exciting cause would probably give rise to deeply-seated abscesses connected with the rectum and forming eventually a most troublesome fistula. To this general rule, I shall, however, presently narrate a well-marked exception.

There is a class of cases presenting all the features of inflammation of the brain occurring in middle life previous to the cessation of the menses, which cases are closely allied to these of abscess. The symptoms presented by the two most marked cases that I have seen, in neither of which had pregnancy occurred for several years, were excessive menstrual discharge, with the sense of prolapsus of both uterus and rectum, increased by standing and defæcation, accompanied by a fixed aching pain, with much tenderness deep in the pelvis in the situation of one or other ovary; there was a feeling of tumefaction in each of the cases, but I could not detect any swelling. This pain continued for some weeks and gradually passed off, though at the menstrual periods they have felt some return of the uneasiness. In a lesser degree the same symptoms occasionally present themselves after marriage or when the uterus has been injected, a proceeding to be *scrupulously avoided* except under circumstances of urgent necessity.

I have not yet found abscess of the pelvis connected with ulceration of the cervix uteri, nor from the nature of that complaint could such a combination be anticipated. The following case *may be* one of this kind, of which, however, though it has been under my observation for years, and occupied my best attention, I am by no means certain; its early stage I have no doubt was ulceration of the cervix uteri in a woman of highly nervous temperament, which disease induced frequent abortion.

CASE VI.

E. H., aged 39, has had ten children born alive, the last five years ago. Her mother died of disease of the womb. In September, 1839, she states that she was attended by a nurse, with twins of about seven months, which lived some hours. After the birth of the first the woman pulled away the placenta, after which the second child was born; from this she gradually recovered. In January, 1840, after unusual exertion she had pain in the hips and back, with occasional discharges of blood. About this time I find her down in my Dispensary book as suffering from metritis. I then knew nothing about ulceration of the cervix. In September, 1840, she aborted at eight months, after

which for some time she suffered from menorrhagia, with constant sense of prolapsus and excessive tenderness of the vagina, and she aborted several times. In January, 1844, she had a living child of about eight months, when she states the placenta was with difficulty removed; the child lived three months, she having no milk. In 1845 she again aborted, not being aware that she was pregnant. Twelve months ago she had quite recovered her health, though not so strong as originally; menstruation being natural and not profuse.

For the last six months she has been losing ground, catamenia have not appeared, but twice she has had a large amount of thick yellow discharge, and occasionally blood in the urine. For the last six weeks, (December 23, 1848,) she has perceived none in it. Throughout her long illness she has suffered from frequent attacks of vomiting, with red glazed tongue and occasional diarrhoea.

Her state in December 1848, was the following:—She complains of pain across the sacrum, hips, and pubes, down the inside of both thighs, especially in the left groin, to the inside of the left foot and ankle; has flitting pain in other parts; has pain in passing a motion; if the bowels are ever so relaxed, she is still obliged to strain with much pain in the anus and sacrum; if the motion is solid and formed it is said to be covered with mucus and slime. Occasionally she need not for a long time relieve her bladder, at other times she must frequently do so; the making water is almost always accompanied by pain above the pubes and through the passage. At uncertain intervals she passes abundantly a thin slightly-coloured discharge, making her linen stiff, starchy, and rusty coloured; this occasionally comes on in gushes without previous notice. She has also a thick yellow discharge streaked with blood, or containing amongst it small clots of blood. She has no bearing down except in the rectum. She is very tender in the left groin and towards the hip. She states that occasionally there is a large oblong swelling in the left groin, which is as apparent when lying down as when sitting up. On vaginal examination I found the uterus enlarged, not fixed, the cervix short and fissured; on the left side it feels knotty as though the veins were enlarged and varicose. The upper boundary of the vagina at that portion of the pelvis corresponding to the left groin is peculiarly tender, no other parts of the canal being so, and nothing special can be detected on the vesical surface. The secretion left on the finger is not unnatural.

In this, as well as the other cases, I have carelessly overlooked the means of diagnosis afforded by examination by the rectum, so that I cannot with confidence quote this case as one of the class I am endeavouring to illustrate, the symptoms during the last six months leading to the fear that cancerous degeneration has arisen in connection with long standing uterine disease.

Abscesses in this region are not confined to the female sex, though in the male they rarely discharge themselves by the natural passages, as in the female, but in the neighbourhood of the rectum, constituting the various forms of fistula ani. The probable reason of this difference is, that in these latter cases the

abscesses are external to the inferior layer of the pelvic fascia, while those internal to the pelvic fascia open into the rectum.

CASE VII.

To Mr. T. Barrett I was indebted for seeing a well-marked case in the male, originating apparently in inflammation of the cellular substance around or posterior to the prostate gland, thence spreading upwards, and secondarily involving the peritoneum, especially its pelvic portion. He kindly furnished me with the following history:—

J. B., aged 16, a thin weakly youth, had been labouring for two or three days, early in April, 1846, under a feverish attack. He then had severe pain in the bowels particularly over the pubes, increased on pressure; the bowels were costive and he had not passed any water for twenty hours. There being some difficulty, at the request of Mr. Barrett, I passed the catheter and drew off about three pints of urine. There was no pain or tension of the perineum. For some days the pain in the bowels and fever continued, and the catheter was passed daily. After a short time he was able to return to his employment, but in about ten days he was again laid up. He had then great and continued pain, much increased on pressure, over the whole of the bowels, but mostly over the right iliac region; he lay on his back with the right leg drawn up and had frequent rigors; he was then labouring under peritonitis. The treatment extended over about a week.

He was about again to return to his employment when ascites set in; this was, however, quickly relieved by mercurial frictions, the pain never having entirely left the right iliac region, that part being very painful on pressure, and there was always numbness down the right leg to the knee. His appetite failed him and he lost flesh daily.

One morning (about four weeks from the first attack) Mr. Barrett was sent for to him in haste. He found him on the night stool very faint and voiding a large quantity from the rectum of very offensive purulent matter unmixed with feces. He had been suddenly seized with desire to pass a motion, and before he could reach the night stool an immense quantity of purulent matter "gushed," as he expressed it, from his bowels. The quantity collected on the bed and in the pan was about three pints and a half. He continued to pass pus for about a week, in quantities varying from four to ten ounces daily, when it suddenly ceased and he recovered his health and resumed his duties.

The pain in the iliac region had been very acute the day before the abscess burst, but he lost it directly the discharge took place.

The patient continued in pretty good health for about ten months, when he had epileptic fits and became imbecile. Since then he has died of phthisis.

Post-mortem examination. April 20th, 1849.—On examining his body there was found a large quantity of fluid within and beneath the arachnoid. The upper parts of both lungs were broken down. In the abdomen there were no traces of general peritonitis, but over

the fundus of the bladder was a corrugated spot the size of a crown piece, and of a dead white colour, continuous with the layer lying on the rectum. The limits of this were almost abrupt; this consisted of the peritoneum much thickened, by the addition of dense cellular tissue on its attached side, the coats of the bladder at this part being correspondingly thickened, so that a section was upwards of a quarter of an inch in thickness; the bladder itself with this exception was healthy. The surrounding peritoneum appears quite healthy, the bladder not being tied down by adhesions, except at the part named. Just above the fundus of the bladder is a fibrous cord, the thickness of a quill, extending from the upper part of the rectum to a portion of the lower ilium, to which it is tied by a broad band of cellular tissue, the upper boundary of which is the above-named fibrous band; on opening the rectum this band had evidently been connected with it, there being a depression on the mucous surface, and a probe could be passed into it; the tissue of this band was much more intimately connected with that of the rectum than with the ilium, which did not present any appearance of an aperture that had closed up. About six inches up the rectum, opposite the thickened peritoneum and fundus of the bladder, were the traces of the abscess, the tissues at one part being hard, and intimately connected with the structure of the gut. The impression, an accurate examination of the pelvic viscera gave me was, that the inflammation had originated in the cellular tissue of the fundus of the bladder, not the prostatic portion as I had supposed, causing its loss of power, and this ended in the formation of an abscess posterior to the fundus, which, having attained a large size, and formed adhesions to the intestine, burst into the rectum. I do not know whether there was any connection with the fibrous band before described, or whether it was not one of those diverticula that occasionally are found attached to the intestines. The mesenteric glands were enlarged, but there was no tubercular deposit.

Through the courtesy of Mr. Findlater Crang, I was enabled to make a *post-mortem* examination of a case of the disease under consideration. Her history, as far as could be gathered, was as follows:—

CASE VIII.

M. A., aged 32, never having borne children, about ten years ago was supposed to have suffered from inflammation of the bowels, when she appeared to be going into a decline; she then much improved in health, and two years and a half ago she married. Four months before her death she supposed herself pregnant, from her increase of size and the severe pain she occasionally suffered in her bowels. About a month before her death she felt a sensation as if something had burst internally, which she likened to the explosion of a pistol; after this there was frequent vomiting, the bowels being then costive. She was not under medical treatment at this time, Mr. Crang being called to her only just previous to her death, February 4th, 1849. On examination the broad ligament on the left side of the uterus was enlarged, puckered, closely matted

together, and adherent to the upper part of the rectum. The left ovary, and the parts immediately around it, formed a large bag of purulent matter, which had opened itself by a round aperture, with smooth defined margins, about twelve inches up the rectum, which gut was deeply injected, and its mucous surface ulcerated in some spots. The uterus was not enlarged, and, with the vagina, bladder, and lungs, were healthy. There were no traces of cancerous or tubercular disease.

The last case which I shall narrate is one for the history of which I am indebted to Dr. Davies, by whose courtesy I was present at the *post-mortem* examination. My object in now quoting it is to show the strong contrast it presents in the severity and urgency of its symptoms to the cases of idiopathic abscess of the pelvis I have thus imperfectly drawn up.

CASE IX.

Elizabeth Chapman, aged 40, the mother of four children, had led a somewhat irregular life; first came under Dr. Davies's observation in the summer of last year. Her health appears to have been good up to the period of her last confinement, which took place three months before he saw her; the labour was a difficult one, and had to be terminated by means of instruments. She stated that sometime after her confinement, when the ordinary discharge should have terminated, there was set up a thin watery discharge, very offensive, mixed for some time with shreds of membranous matter, like soaked brown paper. The shreddy matter had ceased before he saw her, at which time her condition was the following:—Countenance pinched and anxious; much emaciated; skin soft and blanched; bowels irregular, at times relaxed at others much confined; pulse quick and weak; some degree of hectic fever; a thin, watery, offensive discharge from the vagina; examination showed great destruction of the vaginal walls; the uterus appeared of its normal size, the mouth being somewhat open, and the lips everted. She remained in the hospital about two months, when she was discharged at her own desire, being anxious to return to her family. Her general symptoms at this time were considerably improved. Dr. Davies now lost sight of her for about three months, when she again applied for admission into the hospital. In addition to her other ailments she had now a thick purulent discharge from the rectum. She lingered in the Hospital for about two months, when she died, worn out with suffering, and hectic. She suffered much from tenesmus, the pain of voiding her fæces being intense. She also suffered severely from neuralgic pains down the left thigh.

On dissection the body presented a state of extreme emaciation. The arch of the pubes was removed, and the whole of the pelvic viscera taken out. On examining the mass the rectum was found ulcerated and cancerous. In the cellular tissue, to the left side of the rectum, there was a large abscess, involving the sciatic nerves of that side, and which was ready to burst through the skin on the lower edge of the glutans, and communicated with the rectum by means of three ulcerated openings, one as large as a horse-bean, the other two smaller; the edges of the ulcers were thick

and rounded. On slitting the rectum open the whole internal surface was found ulcerated; examination by means of the microscope showed the diseased mass to consist chiefly of fibrous tissue, with a large number of compound cellular bodies, considered to characterize malignant growths. There were, also, numerous exudation globules. The vagina presented a shapeless cavity, nothing of the natural walls being discovered, except just at the upper part. The uterus presented a natural appearance externally, its internal surface was in a state of ulceration. The left ovary was enlarged and lobulated.

To those desirous to investigate this subject I would recommend the perusal of some interesting cases, well described by Mr. Bell, in the 36th and 37th Volumes of the *Medical Gazette*, in which essay will be found references to most of the modern writers on this disease: for my own part I have aimed only to describe such leading features of the cases as may fully identify them, and to draw the attention of the members of the Association to the existence of such maladies, which are more common than they are supposed to be, and which not unfrequently present symptoms of a very anomalous character otherwise inexplicable.

WHOLESALE POISONING BY THE ACETATE OF LEAD.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

I beg to enclose you the accompanying report of cases treated by Mr. Freer and myself, conceiving it will contain matter of interest to the profession.

I have the honour to be, Sir,

Faithfully yours,

THOMAS BANCKS.

Stourbridge, April 21, 1849.

As only some slight notice has appeared in the public prints relative to the late unfortunate cases of lead poisoning in this town and neighbourhood, and from the number of persons attacked and serious character of their symptoms, great interest has been necessarily excited, we deem it of sufficient importance to lay before the profession a few remarks on the subject, more particularly as we find no opportunity has ever before occurred to the eminent authors on medical jurisprudence and toxicology of recording the progress and treatment of so many cases at the same time.

It appears that, from the mistake of a servant employed by a miller in the neighbourhood, from twenty-five to thirty pounds of acetate of lead became mixed with about eighty sacks of flour, and were distributed to the various shops. The persons who partook of the flour, after a few days, complained of a sense of constriction about the epigastrium and throat, with violent crampy pains round the umbilicus, and

much rigidity of the abdominal muscles, a dragging pain in the lumbar region, (this latter was an invariable symptom,) and the lower extremities either cramped or partially paralysed; there was obstinate constipation, and the secretion of the kidneys scanty, and of a deep red colour; the pulse generally was slow and feeble; the countenance anxious and sunken, frequently of a peculiar livid hue; tongue flabby; gums with the characteristic blue line, and where carious teeth existed, the interior of the mouth blackened by the action of sulphuret of lead. The secretion of the skin was, in most cases, checked, and there was little development of animal heat over the surface of the body. Sickness was by no means an invariable or continued symptom, being described by the patients as having existed at first, but in many instances had subsided before medical aid was obtained. The functions of the sensorium remained undisturbed. In the more aggravated cases there was great prostration and collapse, with livid countenance and universal cramps, and numbness and other symptoms sufficiently alarming to call for the exhibition of the most powerful stimulants.

Treatment.—In most cases, from the length of time the poison had been in the system, much benefit could not be expected from the use of the stomach-pump or emetics. We found the continued use of the sulphates of soda and magnesia, largely diluted, most useful. The regular administration of enemata of gruel, with castor oil and turpentine, and where violent pain or cramps existed, in combination with opium. Enemata also, containing the sulphates and common salt, and the greater the quantity the bowels were able to retain, the more speedy the relief. The external application of turpentine, with flannels, and where sickness, (which was not frequent,) a mixture, containing hydrocyanic acid, hyosciamus, and camphor, was given with marked good effect; but we cannot too strongly dwell on the benefit derived from the *continued* exhibition of purgative medicines, the bowels being locked for a single day, was sufficient to produce a relapse. Milk, as an article of diet, was decidedly beneficial in all cases which came under our observation. Some of the slighter cases appeared to vary little from day to day, and to improve very slowly under treatment, the poisonous effects of the lead exerting its influence in keeping down the heart's action, depressing the nervous system, and partially arresting all the secretions. This state was more marked where previous disease of the heart or pulmonary vessels existed. In very many instances, after apparent convalescence for several days, all the symptoms returned in the same aggravated form, without any obvious cause, and up to the present time most of the persons who partook of the flour present a peculiarly pale, unhealthy appearance, but in no instance which came under our observation did inflammatory action ensue; and what is more strange, considering the number attacked in this town and neighbourhood, (upwards of 500,) and the violence of the symptoms of so many, not a single fatal case occurred.

It is impossible to conjecture the quantity taken by each person, it being very unequally mixed; and

several samples of flour and bread brought for analysis presented no trace of lead, whilst others were strongly impregnated with it. The secondary symptoms,—viz., paralysis, &c., &c., from which no doubt many will suffer for a considerable period of time, shall be laid before the profession in due course, together with the treatment which may be found most beneficial.

Hospital Reports.

WEST NORFOLK AND LYNN HOSPITAL.

COMPLICATED SURGICAL CASES UNDER THE CARE OF CHARLES COTTON, M.D., F.R.C.S., &c.

CONGENITAL CARCINOMATOUS TUMOUR: EXTIRPATION AT EIGHTH WEEK: SUBSEQUENT REPRODUCTION, AND DEATH.

William Howard, aged two months, a fat, plump, but rather pallid-looking infant, admitted, together with the mother, November 21st, 1846.

At birth, a lump as large as a walnut was observed on the inner side of the left arm. This had continued to increase rapidly to its present size. On examination a dense, elastic, moveable, irregularly-shaped tumour was found above the bend of the elbow, measuring seven inches in circumference, the surface of which, at a point below the centre, was of a reddish livid colour, but the handling of the swelling caused no apparent discomfort. The mother, though delicate, enjoys pretty good health. The father was reported as being subject to eruptions, but on being requested to present himself, they were ascertained to be only of a trifling scorbutic character.

November 25th. In the absence of any detectable axillary or other glandular enlargement, it was thought right, in consultation, to give the child the chance of an operation. The removal was accordingly at once proceeded with, and quickly effected, by an incision in the mesial line, directly down upon the tumour, commencing and terminating at a short distance above and below it. The integumentary and fleshy connections were then steadily detached by means of the scalpel and finger, and a further strong unyielding fascial-like attachment at the base of the tumour, divided by cutting close to the bone. Two ligatures were applied to the spouting vessels, and not more than two table-spoonful of blood escaped during the operation, at the conclusion of which the countenance became extremely pallid, respiration and circulation faint, and a state of death-like exhaustion ensued; but by being kept in the recumbent position, and carried quickly into the cool air, and by the use of other simple measures, the child shortly revived, and on being placed in bed was, after a few minutes, enabled to be refreshed by small portions of milk dropped into its mouth from the breast of the mother. The edges of the wound were suffered to fall together, surrounded by a bandage. One drop of Battley's sedative in syrup to be given if restless or uneasy.

26th. The child slept soundly from the effects of one dose of the sedative, and excepting being pale, appears no worse from the operation.

27th. Bandage, previously moistened, removed. Water dressing.

December 5th. Had gone on well; the central part of the wound soundly healed; the extremities suppurating, and kindly granulating. Ordered to take the following mixture, and to be an out-patient.

R. Liquoris Potassæ, m. xx.; Magnes. Calcinat., gr. x.; Tinct. Opii, m. iv.; Syr. Aurant. dr. iv.; Aquæ Carni ad oz. ij. M. Sumat, cohl. parvum ter in die.

January 30th, 1847. Child thriving and healthy; wound quite healed several days since. Go on with the mixture.

March 3rd. The patient privately seen; malignity of tumour settled. A small indurated secondary formation beginning at the lower end of the cicatrix. Mother directed to attend again at the Hospital.

10th. Consultation, owing to the healthy appearance and condition of the child, rather in favour of operative procedure. The mother giving but an unwilling consent from a negative hope of cure held out to her, further surgical interference was withheld.

R. Sumat Iodidi Potassii, gr. j., cum sing. dos, Mist. To remain an out-patient.

June 22. An additional tumour rapidly formed, involving the upper part of the scar, numerous blood-vessels ramify over its surface, the integuments are of a purplish colour, and the whole forms an irregularly-shaped mass exceeding the size of an orange. Child still fat and plump, though pale, and seems in no way inconvenienced by the disease.

Shortly after this report, the integuments gave way and a bleeding fungus sprouted forth, the hæmorrhage from which was occasionally and temporarily restrained by matico or alum. The child soon became sallow and cachectic, and rapidly emaciated, and owing to his living a distance from the Hospital was lost sight of up to the period of his death, (Sept. 5th,) when the mother presented herself to return thanks, and stated that her infant had died, "worn out" and exhausted by the bleeding and disease, in the twelfth month of its age and upwards of nine months after the operation.

The congenital origin, nature, and rapid growth of the tumour up to the second month, together with the hazard arising out of an operation upon a child so young, and the subsequent recurrence of the disease, excited considerable interest in this case.

Looked upon as an evidence of general constitutional vitiation, the removal of the tumour was not undertaken without great apprehension of local or other distant reproduction, and it was only in the absence for several weeks, of any manifestation of return, that hopes began to be entertained of the disease being of a more innocuous character than was anticipated, when the *new formation* was observed in the course of the cicatrix, and led to the question of further ablation or amputation, and the determination (under such unpromising circumstances, and in deference to the mother's wishes,) to leave it undisturbed. The progress and termination of the case affords an additional instance of the common and surely deadly effects of the cancerous molecule, wherever deposited, and whatever be the age of the victim, and also accords with the lamentably unsatisfactory experience of many surgeons, who, in the course of operative practice have extirpated cancerous tumours in their several stages of development, and who, but for the uncertainty of diagnosis,

look with faint hope for lasting restoration and extermination, from the ablation of true scirrhus or encephaloid formations.

Previous to the re-appearance, and whilst a doubt of the positive nature of the disease existed, *the tumour*, suspended in spirit, was forwarded to London for microscopical inspection. It presented an irregularly lobulated appearance, and on a section being made,

was found of a firm sarcomatous structure, having several rounded slightly softened vascular patches, of a livid red colour, "*simulating early fungus hæmatodes.*" By some unintentional negligence, so desirable an analysis was not obtained, neither was the preparation exhibited at the Pathological Society, as promised, nor has it up to the present time been returned to the hospital.

PROVINCIAL
Medical & Surgical Journal.

WEDNESDAY, MAY 16, 1849.

THE painful task devolves upon us, as a Committee of the Worcester Council, to communicate to our readers the melancholy intelligence that the respected Editor of this Journal has written his last line in the service of the Association.

Dr. Streeten had been suffering for some months from a bronchial affection, the consequence of an attack of influenza which seized him in the early part of the month of January. This left him in a very weak state of health, for which he was induced to try the air of Torquay; here, however, a new train of symptoms supervened, implicating the alimentary canal. For some days he was distressed with continual vomiting, which seemed to relieve the bronchial symptoms, but never entirely left him, and he gradually lost flesh and strength up to the day of his decease, which took place on Thursday evening last.

The occurrence of his death so near the day of publication precludes our giving that detailed notice of his able, untiring, and indeed invaluable services in aid of our Association, which we hope to do in a future number; we must, therefore, content ourselves with the simple announcement, that in consequence of his serious illness, the Worcester Council at their last meeting, appointed a Committee to discharge those duties previously intrusted to him. These we will endeavour to perform until the Annual Meeting, if not so ably as by our late and lamented Associate, yet we trust to the satisfaction of the members of the Association, when they take into consideration the melancholy circumstances of the case.

CHOLERA has within the last few months visited us for the second time, and for the second time is now on the eve of abandoning our shores. It may be useful therefore to enquire, how far this renewed invasion of the disease has enlightened us as to its nature, and whether we have attained to any improved method of treating it? If the number of publications which have appeared since its introduction were to be received as a criterion of the progress made in its investigation, then surely must cholera be unravelled even to its inmost mysteries, for never we should imagine, has there been known a more generally diffused spirit of authorship than this very subject has evoked. The grey-headed nestors of the profession, the mature and still active-minded physician, and the ambitious tyro, have all and each contributed their quota of print. Sundry musty tomes, snatched from the inglorious dust of the printers' shelves, where they had lain in neglected solitude since the date of the last epidemic, have again struggled into notice on the strength of a new covering or a new title page. Additional volumes have also appeared in abundance, and pamphlets and papers without end swell the amount of choleraic literature. But, we again ask, are we from this deluge of writing one whit better acquainted with the nature and treatment of the pestilence than we were in 1832. Our impartial review of what has been advanced, compels us to reply in the negative. Take any given number of the more recent communications, and do we not find the same discrepancy of opinion, as to the nature of cholera, as existed during the previous outbreak? We find now, as then, one writer safely enough contending that it is a disease of the blood; another likens it to the cold stage of fever; a third calls it inflammation of the semilunar ganglia; a fourth a perverted condition of the natural galvanic action of the human body. Even on the subject of its transmission and propagation, which needs only careful enquiry for its solution, there is no nearer approach to unanimity. One section of writers

see ample evidence of contagion, where another can discover nothing but atmospheric influence. A third party, of no small importance in this realm, with a marvellous confusion of ideas, decide that it is not contagious, but think it requisite to throw the most serious impediments in the way of commerce, with the express object of preventing communication between the healthy and infected. And then, as regards treatment, how painfully bewildering is the difference of opinion! We have calomel in scruple doses, and calomel in one-grain doses; calomel without opium and with opium; we have acetate of lead and croton oil; cold water *ad libitum* and total privation of drink; bleeding and transfusion of blood; hot baths and cold affusion; naphtha, chloroform, tartar emetic; in fact, there is scarcely an ingredient in the Pharmacopœia, but has found some advocate on the strength of one or two successful cases.

This glaring inconsistency among those who have taken upon themselves to enlighten us on the subject of cholera, is not less unfortunate for medical science, than it is discreditable to the logical reputation of its professors; and gives but too good cause for the enemies of legitimate medicine to blaspheme. The difference of opinion is doubtless to be referred to the intricacy of the subject, but of this the public mind takes no account; we have lost so much of the "divinity which did hedge round" a doctor; and both the art we practise and those who practise it, have become of late so vulgarized, that little is required to elicit the stale joke of "doctor's differences," or the more refined sarcasm of the "uncertainty of medicine." It would be well if those who write on any great question of public interest, such as cholera, would consider how unfavourable to their calling, on the public mind, is the enunciation of a series of crude speculations, (which must necessarily lead to as many varieties of opinion and conduct as there are writers,) and would not allow the passion for individual notoriety to swamp their love and reverence for the profession itself, every insult to which they should feel as a personal injury.

In these criticisms upon the recent writings on cholera, we purposely avoid distinct allusions to particular authors. Many of these writings bear evidence of being the production of cultivated and thoughtful minds, and are composed in the spirit of honest enquiry; but others, it is too plainly observed, have been put forth

with less commendable motives. On the whole, the profession has reason to be disappointed in the amount of useful information, which has been elicited by the experience afforded on the recent pestilential visitation. It found us ignorant of its natural history and treatment and it has left us so.

Proceedings of Societies.

BIRMINGHAM PATHOLOGICAL SOCIETY.

February 1st, 1849.

W. H. PARTRIDGE, Esq., in the Chair.

ULCERATION OF PEYER'S GLANDS AND SOLITARY GLANDS OF THE COLON.

Dr. Fletcher gave the particulars of the following case:—

John Pugh, aged 16, a boatman, was admitted a patient at the General Hospital December 12th, 1848, suffering from fever. He was an emaciated miserable-looking man, in a state of collapse, and had been brought a long way from the country. It was stated that he had been ill only nine days. Tongue dry and brown; pulse 120, weak; thirst, and low muttering delirium; a flattened state of the abdomen, painful upon pressure, especially in the ilio-cæcal region; diarrhœa; bronchial râles at the posterior parts of the chest were the symptoms which presented.

He was ordered stimulants, and small doses of Hydrargyrum cum Creta, and Compound Ipecacuanha Powder, to be repeated about every four hours, after which the diarrhœa and the bronchitis were diminished, and the pulse reduced in frequency.

On the 15th signs of sinking began to appear, accompanied by abdominal tympanitis, in consequence of which the stimulants were increased, and a turpentine injection administered.

16th. The diarrhœa came on with increased violence, and on the following morning, having been previously seized with extreme dyspnoea, he sank.

Autopsy twenty-four hours after death.—*Body* much emaciated. *Head* not examined. *Thorax*: Both lungs highly engorged; the bronchial mucous membrane universally injected; the posterior portion of the inferior lobe of the left lung condensed and friable. The heart flabby. *Abdomen*: Nothing remarkable in the liver or stomach; the spleen enlarged, and so soft as to be almost diffuent; the whole intestines presented a general increase of vascularity; the lower portion of the ilium was crowded with superficial ulcerations of Peyer's glands; the ilio-cæcal valve was thickened, and slightly ulcerated; there were small superficial ulcerations in the ascending colon; and the glands generally of this intestine were in a highly congested and hypertrophied condition. The kidneys and the primary organs were healthy.

ULCERATION OF LARYNX: EPIGLOTTIS DESTROYED: TUBERCLES AT THE APEX OF THE LUNG.

Dr. Fletcher also narrated the following case:—

Thomas Capewell, a labourer, aged 34, was admitted as a patient into the General Hospital, November 10th,

1848, affected with laryngeal phthisis, from which he had suffered for some months. He was much emaciated; voice so husky that he could only speak in a whisper; had cough and purulent expectoration, and had had hæmoptysis a month since; pulse quick; night perspirations; dulness beneath the left clavicle on percussion, where the breathing was bronchial; and there was bronchophony. R. Infus. Calumbæ, oz. viij.; Tinct. Hyosci, dr. ij.; Acid. Hydrocy, Dil., m. xx. M. Cap. oz. j. ter indies.—R. Pil. Conii Comp., gr. v.; Pil. Hydrarg., gr. iij.—M. Et divide in Pil. ij., hora somni omni nocte sumend.—R. Argenti Nitrat. Crystallarum, scr. iv.; Aquæ Distil., oz. j. M. Fiat solutio.

About every third day the interior of the larynx and the neighbourhood of the epiglottis were touched with this solution by means of a small round sponge, fastened to the end of a piece of whalebone, curved so as to form the end of one quarter of a circle, of which the diameter was four inches, whilst the tongue was strongly depressed by the angular spatula; in fact, exactly the topical treatment was adopted which has been so strongly recommended by Dr. Horace Green, of New York, by which the patient was afforded very great temporary relief, and his voice rendered nearly natural. Signs of softening of tubercle became more and more evident under both clavicles, the night perspirations and debility became extreme, and he died on the 5th of December.

Autopsy twenty-four hours after death.—*Body* extremely emaciated. *Head*: Nothing morbid in the brain. *Larynx* presented the following appearances:—Great thickening of the epiglottidean folds, and general condensation from exudation into the submucous tissue of the structures around the rima glottidis; the true and false chordæ vocales were approximated; the ventricles of the larynx were almost obliterated; ulcerations were found on the posterior points of each of the true chordæ vocales, close to their attachment to the aryteroid cartilages: they were covered by a caseous matter, which resembled tubercle; the epiglottis was destroyed by ulceration; the whole mucous membrane of the larynx and trachea was vascular and thickened, and covered by mucus. The *lungs* were very large and generally loaded with milary tubercles, the apices of both presented cavities, varying in size from a hazel-nut to a walnut. *Abdominal viscera* healthy. *Kidneys* large and congested.

This case Dr. Fletcher brought before the Society on two considerations: on the one hand as an example of the great extent of the ravages of the ulceration in the larynx in some cases of phthisis; on the other, to shew the good effect of the application of a strong solution of the crystals of nitrate of silver, according to Dr. Green's plan, which in this case, (notwithstanding the very extensive disease,) had given great temporary relief to the patient, and almost restored his voice to its natural state. To the good effects of this plan Dr. Fletcher was anxious to bear testimony, having seen great benefit resulting from its application in many cases of phthisical and syphilitic laryngitis.

TWO FATTY KIDNEYS; A SMALL CONGESTED LIVER, AND THE HEART SMALL, WITH ONLY TWO AORTIC SIGMOID VALVES.

Dr. Fletcher narrated the following case:—

Ann Smith, married, aged 45, admitted as a patient into the General Hospital on the 18th of August, 1848, suffering from general anasarca, albuminuria, and disease of the cardiac valves. She has been ill some months. She is a small spare woman, of a pale and pretty countenance; tongue clean and moist; pulse quick and feeble; anasarca of the lower extremities, and of the abdominal parietes, of a very firm and gelatinous character. She complains of no particular pain; has no cough or expectoration; has slight dyspnoea on exertion and the first thing in the morning.

The history she gives is that she had an ovarian enlargement about twenty years since, that she had rheumatism severely affecting the joints five years since, and that last Christmas she suffered from influenza, when the dropsy first appeared, and has continued ever since. She has not menstruated for two years. The chest is resonant upon percussion, and the respiratory murmur natural in all parts. A soft systolic murmur is audible opposite the sigmoid vales of the aorta, and in the course of the ascending aorta, extending upwards to beneath the right clavicle. Towards the heart's apex a similar murmur, somewhat fainter, is also audible. Urine of specific gravity 1012, strongly albuminous, on the application of heat and nitric acid, and fibrinous casts, with fat globules attached to them, were found in the urine on examining its sediment with the microscope.

She was ordered one-twelfth of a grain of elaterium every four hours, until watery motions were produced, and this action to be kept up as far as consistent with the state of the strength of the patient. Milk diet, light pudding, and arrowroot.

This plan was pursued, with great benefit to the patient, until the 5th of September, when it was thought right to give her a little beer daily. On the 7th a vapour-bath was ordered every other night. On the 9th a glass of wine daily, with the following mixture:—R. Ammon. Sesquicarb., scr. ij.; Mist. Camphor., oz. viij. M. sumat, oz. j., ter die.

On the 18th she was discharged. Scarcely any œdema remained. The sounds of the heart and lungs remained the same. Her strength had been reduced by the operation of the elaterium.

On the 8th of November Ann Smith was re-admitted. Her symptoms existed in an aggravated form; face extremely anæmic; body universally anasarca; urine thoroughly albuminous, specific gravity, 1025. The urine remained albuminous, but became of lower specific gravity; casts of tubes, studded with fat globules, were found in the sediment of the urine, and were found, all through the case, on examination with the microscope. She had several attacks of bronchitis, during which, owing to the ascitic fluid pressing upon the diaphragm, she suffered extreme dyspnoea.

On the 19th of December signs of effusion into the right pleura existed, when the dyspnoea became greatly aggravated. The treatment consisted of frequent small doses of elaterium (from which the patient derived the

greatest benefit, both with respect to relieving the dyspnoea, and lessening the anasarca and effusions generally,) blisters to the chest, and occasionally small portions of wine. In the early part of December she was acupunctured in the left thigh, from which great relief from the distension was attained, by the constant oozing of water from the minute orifices. A slight erythematous blush appeared on the surface of the thigh, and she had acute pains in that limb. She experienced great relief from the application of cotton wool.

On the 3rd of December she was acupunctured in the right arm for great distension, and at this time severe dyspnoea came on from a renewed attack of bronchitis, from which she sank on the following day.

Autopsy twenty-four hours after death. Body generally anasarcaous. *Head*: Nothing abnormal in the brain. *Thorax*: A large quantity of lemon-coloured serum in the right pleura. Both lungs much congested. The mucous membrane of the bronchial tubes highly injected, and loaded with mucus. Both lungs were below the normal volume. The heart very small, it weighed only four ounces. All its cavities and orifices were smaller than natural. The aortic orifice much contracted, its valves small and thickened, and consisted of only two divisions. *Abdomen*: Liver small and congested, of a general yellow hue; it weighed only two pounds and a half. The abdominal cavity contained a large quantity of transparent serum. The spleen had a recent coating of lymph on its surface, otherwise healthy; it weighed five ounces. The kidneys were much above the normal size, but less firm than natural; the whole cortical structure of a pale yellow colour; the outer surface, from which the capsule was with difficulty stripped, was of the same colour. The microscope revealed a mass of fatty granules throughout the structures of the kidney, free, and within the tubuli.

ANEURISM OF THE ASCENDING AORTA; DILATED AND HYPERTROPHIED HEART; LYMPH IN THE PERICARDIUM AND DISEASED AORTIC VALVES; CONDENSED RIGHT LUNG; LARGE AND CONGESTED KIDNEYS.

Dr. Fletcher gave the following history of the case:—

—Wood, aged 38, a discharged cavalry soldier, was admitted an in-patient of the General Hospital on the 9th of January, 1849, after having been for a few days an out-patient. He was a tall man, of large frame, had been eighteen years in the cavalry, and was discharged from his regiment with an excellent character two months since, from his inability to perform his duties. Eight months ago he first began to suffer from dyspnoea and cough, which he attributes to exposure to wet. He never had any attack of rheumatism. A month after the dyspnoea first appeared his abdomen began to swell. Four months since the legs became oedematous. He never lost blood. He is married and had never committed any excesses.

He now suffers from intense dyspnoea, so that he can scarcely breathe except when sitting up; has a little expectoration but no cough. His hands, legs, and abdomen are very much swollen from effusion; the skin of the feet has given way in two places, from which water is discharged in small quantities; tongue clean; appetite

bad; bowels free; he passes about a pint and a half of urine in twenty-four hours; pulse 112, small and wiry, and equal at both wrists.

On examination of the chest by percussion the right side is dull all over, but less so at the apex, and all over posteriorly for about four inches from the spine. The left side is very clear with the exception that the dullness of the precordial space is manifestly increased. On auscultation the respiration on the right side is found to be extremely feeble—scarcely audible; it is bronchial in its character, and accompanied by very obscure mucous crepitation, particularly at the lower part of the axillary region; the noise is abnormally resonant in the upper part of the front of the right side of the chest. On auscultation of the lungs of the left side of the chest, the respiration is found puerile in its character. The heart's impulse greater than normal, and both sounds accompanied with a harsh murmur, rubbing, and superficial in its character; these sounds were heard with great distinctness all over the front of the chest, particularly over the right infra-clavicular region, extending from the upper-third of the sternum. In this situation the sound is particularly loud and rubbing; and it has been remarked that here the sound is comparatively less dull upon percussion than inferiorly. Decubitus is markedly on the right side. The right hypochondrium dull and tense; the hepatic dullness extends to about three inches below the borders of the cartilages of the ribs. Urine highly albuminous. Epithelium scales, and amorphous urate of ammonia, are revealed by the microscope.

The diagnosis in this case is—pericarditis, valvular cardiac disease, with hypertrophy of the heart, desquamation, nephritis, emphysema of the right pleura, limited by adhesion of the lung, anasarca.

As an out-patient he had been blistered, and treated by mercurials, but he was so exhausted by coming to the hospital that it was thought right to give him the following slight stimulus:—R. Spt. Ammon. Aromat., m. xx.; Vini. Ipecac., dr. ss.; Syrupi Papaveris, dr. j.; Mist. Camph., oz. iss. M. Fiat haustus statim sumendus. And he was at once ordered to his bed.

10th. Dyspnoea very great, and decubitus on the right side, and all other signs of disease in exactly the same state. He seemed much less exhausted, having had some sleep. R. Hydr. Chlor., Pulv. Digitalis, Opii Pulv., Extr. Hyoscyamus utr., gr. j. M. Fiat pilula nocte maneque sumenda.—R. Tinct. Scillæ, Potassii Iodidi, Tinct. Digitalis utr., dr. j.; Mist. Camph., oz. viij. M. Cap. cochlearia magna ij., quartis horis. Empl. Lyttæ Sterno applicatur.

11th. Dyspnoea rather relieved; he expresses himself as better; the urine is increased in quantity, and is now found to become opaque by the application of heat, and to clear up again by adding nitric acid. Pergat.

12th. In the early part of the morning he appeared much better, and, soon after taking some drink, he said he felt inclined to sleep, and requested not to be disturbed, almost immediately after saying which he died. He was lying on his right side, with his head low.

Autopsy twenty-four hours after death.—*Head*: Nothing abnormal in the brain or membranes; each ventricle contained about two drachms of nearly colourless

fluid. *Thorax* : The right pleura contained about two quarts of straw-coloured serum : the fluid was contained in a sac, formed by false membrane, and occupied almost the whole anterior, the axillary, and the outer part of the posterior regions of the right side of the chest ; the anterior portion of the superior lobe of the right lung was pulled forward, elongated into a long conical process, and bound down by an old and firm adhesion to the anterior part of the diaphragm, which pulled this part of the lung over, so as to sit like a cap upon an aneurism of the ascending aorta about to be described ; the superior lobe of the lung, with its elongated process, was in a state of carnification, and adherent to the thorax by means of a thin false membrane ; the lower and middle lobes were almost everywhere crepitant, placed close to the spine, and adherent to the posterior part of the thorax : they were very diminished in size, the whole organ was not half its normal size ; the left pleura contained a small quantity of fluid ; the left lung was healthy, and filled its corresponding cavity. The sac of the pericardium contained nearly a pint of lemon-coloured serum ; on the roots of the large vessels there were a few flakes of soft lymph. There were on various parts of the external surface of the heart marks of old pericarditis, consisting of opaque white patches of thickened membrane, particularly on the anterior surface of the left ventricle ; the heart was greatly enlarged ; the left ventricle had nearly double its ordinary capacity, and its walls thickened : it was filled by a large quantity of dark semi-coagulated currant-jelly-like blood, in appearance very much like the ordinary contents of an aneurism ; a less quantity of this was found in the left auricle ; the cavities of the right side contained only the usual fibrinous clots ; all their cavities were equally enlarged with the left ventricle, but their walls were not hypertrophied to the same extent ; the orifices of the right side and the mitral were larger than natural, but without any morbid deposit on their valves ; the aortic sigmoid valves were thickened and corrugated, and did not approximate, so that a stream of water could be poured through a triangular space left between the free edges into the ventricle ; the orifice was enlarged, so as to admit of three fingers being passed through it. The whole ascending aorta was greatly dilated by an aneurism, springing chiefly from its right, and partly from its posterior side, capable of holding a moderately-sized orange ; the dilatation commenced immediately above the valves, and ended abruptly just at the point of origin of the arteria innominata ; the aneurism extended into the right side of the thorax, and lay in the root of the right lung, in close juxtaposition with the pulmonary veins ; the superior lobe of the lung fitted like a cap over its upper, posterior, and right sides, and partly overlapped its anterior surface, over which it appeared to be bound by the long and old adhesion before referred to. The superior vena cava was attached to the artery, but did not appear to have suffered compression. There was a small clot, composed of laminated, fibrinous, and discoloured blood, in the interior of the aneurism, and a small quantity of the currant-jelly-like blood, but it was flabby, and appeared as if its contents had escaped. The coats of the aneurism and ascending aorta were thin, brittle, and lined by masses of

atheromatous and calcareous matter in flakes ; the arch of the aorta, its great vessels, and the descending aorta, were perfectly healthy. *Abdomen* : The liver enlarged, and extending nearly to the umbilicus : its capsule thickened, and abnormally adherent to its surface, which exhibited a slight tendency to granulation ; the whole of the structure of the liver of a nutmeg colour, weight four pounds and an ounce. The mucous membrane of the stomach much injected. The spleen large and congested, its weight eleven ounces. The pancreas enlarged and flabby. The right kidney was abnormally voluminous, it weighed ten ounces, its whole structure much congested, particularly the cortical, which much encroached upon the pyramidal cones ; the capsule was snipped with difficulty. The surface of the kidney presented a uniformly dark red tint. The left kidney was in an exactly similar state, its weight seven ounces.

Dr. Fletcher said that this most interesting case had very closely fixed his attention, and he thought the state of the patient had been pretty fully made out, in fact all the various affections had been clearly indicated, with the exception of the aneurism of the ascending aorta. From this being so masked by the other affections, and from exhibiting no positive characters peculiar to the presence of aneurism, it is very doubtful if that disease could by any possibility have been detected ; at the same time the loud and rubbing sound which was discovered in its situation, served to indicate that there was more extent of surface for friction of the pericardium than in the normal state of that region ; and if there had been the slightest other circumstance to indicate the existence of an aneurism, that must have had its due weight in a diagnosis. The death of this patient was curious, and the circumstance of the regurgitation of the chief part of the contents of the aneurism through the patent sigmoid valves into the left ventricle. Dr. Fletcher at first thought that this must have taken place by means of a rupture of the aneurism into the right pulmonary veins with which it was closely in contact, but on examination he could find no such communication ; it appeared as if by some effort of the patient to place himself in a comfortable situation for rest, which he seemed much inclined to take, he had produced pressure upon the right side upon which he was lying, and that this, through the fluid which that side contained, was communicated to the parietes of the aneurism, and had the effect of compressing it, and emptying it of its contents which regurgitated into the cavity of the left ventricle. It must be borne in mind that the lung was found in a very incompressible state, so that from the state of the contents of the right side of the thorax, it is very fair to conclude that any external pressure upon the parietes of the chest might readily be communicated to the aneurism.

(To be continued.)

MEDICAL LEGISLATION.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND
SURGICAL JOURNAL.

Sir,

As a memorial of some of the Manchester medical men has appeared in our Journal, I beg to forward you a copy of a letter I have written to the Secretary of State, concluding it will be thought just, that as one opinion on this matter of Medical Reform has been published in our columns, all sides of the question should appear there.

I remain, dear Sir, yours faithfully,
GEORGE KELSON.

Sevenoaks.

(Copy.)

Sevenoaks, April 27, 1849.

Sir,—I humbly, yet most earnestly, beg to claim your most serious consideration on the long contested subject of Medical Reform.

I was deeply interested, and most actively engaged, in a memorial presented to you in 1845, imploring you to preserve *intact* the present Charter of the Royal College of Surgeons of England.

This said memorial I beseech you carefully to *re-peruse* and consider. To it were attached the signatures of many medical men,—men of great worth and influence in the medical world, residing in various parts of the United Kingdom. Their respective commands for their signatures I still possess, and if I could imagine it possible a doubt could be cast upon their integrity of purpose, or their anxiety for the cause, or their capability of judging in this matter, I would boldly suggest that inquiry be made into the character and position of every person whose name is attached to this said memorial, and that their petition do stand or fall by the result of the inquiry.

I still urge you, Sir, to preserve this said Charter *intact*.

I so far agree with my professional brethren of Manchester, who have lately memorialized you, that "no satisfactory reason exists for the establishment of a College of General Practitioners in England."

I am confident such an establishment would place not only surgery, but also the profession at large, in a most anomalous and confused condition, and that it would be prejudicial and injurious both to the profession and to the public.

If *Reform* be required, I fearlessly assert it must commence with medical men themselves, who should be Christians and gentlemen; all of them who are not such should be entirely unnoticed by those who maintain a correct conduct.

If *illegal practice* is to be put an end to, let it be clearly defined what is not legal practice, and let the mode of punishment for illegal practice be rendered as facile as possible, by the recovery of penalty after penalty in the County Court.

Registration in England, different from what now exists, cannot be required. The Royal College of

Physicians prints a list; the Royal College of Surgeons prints a list; the Worshipful Society of Apothecaries prints a list.

If the *Curriculum* of education do not meet the views and the necessity of the day, let it be altered by the *Board of Examiners*. Surely this, in reference to General Practitioners, can be effected as efficiently by the existing Board of Examiners, as it would be by a Board formed of other medical men selected from the same *order* of the profession.

I beg particularly to call your attention to the "*Board of Examiners*." With all due respect for, and deference to, the present Board of Examiners, of such as now seek legally to become General Practitioners or Apothecaries, (and I know this Board to be composed of "good men and true,") I do think here there might be a great improvement, even though a short Act of Parliament might be required to accomplish it,—viz., let the present Board be empowered to add *Professors* of the various branches of examination, leaving to the members of the Board themselves, if they desire it, the examination practically in physic, and, certainly, the general controul of the Board.

This suggestion, with, at least, equal force, will apply to any other Board of Examiners formed of General Practitioners, because General Practitioners, of sufficient age and ability to be qualified for this undertaking, may naturally be supposed to be so much engaged in practice, that they cannot have leisure to keep pace with "the times" in the study of the minutæ of science; whereas, a *Professor* who is daily *teaching*, is *hourly learning*; and is thus alone fitted for an examiner in the various branches of the profession.

I have the honour to subscribe myself,

Sir,

Most respectfully,

Your obedient servant,

GEORGE KELSON.

To the Right Hon. Sir George Grey, Bart.,
&c. &c. &c.,
Whitehall.

SUBSCRIPTIONS OF POOR-LAW MEDICAL OFFICERS.

To the Poor-Law Medical Officers of England and Wales.

Gentlemen,—Several of the contributors to the fund for defraying the expenses incidental to the proceedings of the Committee of Poor-Law Medical Officers, have expressed their wish that the names of those gentlemen who have subscribed should be printed, in the hope of others being thereby induced to contribute.

We have reason, however, to know that other gentlemen would wish their names *not* to appear in print. Under these circumstances the Committee refrain for the present, at least, from printing a list of the names of subscribers.

At the same time that the Committee desire to express their thanks for contributions received, they

beg to state, that there being 2914 Poor-Law Medical Officers, they have received 343 subscriptions only, since the meeting on the 19th February, and of these, several were from gentlemen who had subscribed once, and in one instance twice, before.

It is hoped, therefore, that those gentlemen who have as yet contributed nothing, will not consider themselves as excused from assisting, in however small a degree, the fund for the purposes already stated.

I have the honour to remain, Gentlemen,

Your obedient servant,

THOMAS MARTIN,

Treasurer to the Committee.

Reigate, April 30, 1849.

INTRAMURAL INTERMENT.

To the Honourable the Commons of the United Kingdom of Great Britain and Ireland in Parliament assembled.

The Petition of the President and Council of the Gloucestershire Medical and Surgical Association,

Showeth,—

That your Petitioners are of opinion that the interment of the dead in towns and populous districts is *highly injurious to the public health*, and that no measure of Sanitary Reform is complete unless this obnoxious system is *at once and for ever abolished* by legislative enactment.

That your Petitioners desire to express their unfeigned satisfaction that this national grievance was the subject of inquiry by a Committee of your Honourable House in the year one thousand eight hundred and forty-two, who reported, that “after a long and patient investigation, your Committee cannot arrive at any other conclusion than that the nuisance of interments in large towns, and the injury arising to the health of the community from the practice, are fully proved.”

That, from the evidence adduced before the Committee, and the many subsequent exposures of the lamentable and terrible consequences resulting, and necessarily arising, from the present system of interment, your Petitioners venture to express their earnest desire, that the burial of the dead in the midst of the living may be prohibited by the closing of all burial places in cities, towns, and populous districts, and by the adoption of such measures as may secure the public from the injurious and debasing practices at present existing.

That your Petitioners cordially support the efforts now making by the National Society for the abolition of burials in towns, and they desire respectfully to add their testimony and influence, as experienced medical practitioners, in aid of a measure at once politic and humane, and worthy of an advanced civilisation.

NOTES ON AMERICA: ITS MEDICAL SCHOOLS AND ESTABLISHMENTS.*

By EDWARD HUMPAGE, Esq., M.R.C.S., Bristol.

QUARANTINE ESTABLISHMENT: CHOLERA: YELLOW FEVER: GASTRO ENTERITIS.

In the beautiful Bay of New York lies Staten Island, which from its lovely situation is the resort of many of the wealthy citizens, especially in the summer season, at which time the air is so much cooler than in the neighbouring city. The splendid villas of the merchants rise in all imaginable shapes on the fine slopes of the western extremity of the island, and add much to the surpassing beauty of this magnificent bay. Here also is the Government Dépôt for invalids, as they arrive on board the various emigrant ships from Europe. It is a most extensive range of buildings, and is known as the “Quarantine Ground,” comprehending a Marine Hospital, for the reception of patients suffering from contagious diseases, a department for yellow fever, a small-pox hospital, besides several other buildings for the use of the physicians, health officer, and others. The whole establishment is on a very large scale, and will afford accommodation for 1000 invalids. By the politeness of two of the medical officers, Dr. Whiting and Dr. Cucha, I had the privilege of visiting this excellent establishment on two or three occasions.

By the laws of the State of New York, all foreign ships entering the bay must cast anchor on the Quarantine Ground, hoist the yellow flag, and be subjected to an examination by the health officer, who, on finding the crew and passengers healthy, gives a certificate that admits them into port. This precaution is highly necessary, from the multitudes of emigrants constantly arriving from Europe, among whom ship-fever so frequently prevails. All cases of diseases are immediately removed into the hospital, so that sometimes they have a sudden accession of patients, amounting to three or four hundred, the great majority being Irish or Germans. On my first visit I saw a large number of the latter just imported from Bremen; they were suffering from fever and dysentery. The treatment adopted is very simple, such as abdominal fomentations, small doses of grey powder, with Dover's powder at night, and chalk mixture or salines, according to circumstances. When there is much cerebral disturbance, the head is shaved, and ice or evaporating lotion is used; depletion is not well borne, and rarely or ever practised. Much importance is attached to *ventilation*, which is practised to an extent very far beyond that adopted in English hospitals, and the temperature of the wards is usually sixty degrees,—never more than sixty-five degrees, Fahrenheit.

The different apartments being constructed of wood, openings, about two feet by one, are cut in the walls, at intervals of twelve or fourteen feet, just above the floor; these openings being opposite each other, afford a fine current of fresh air; and the same arrangement

being adopted near the roof, most completely prevents any accumulation of foul air, and thus the fresh air becomes a constant remedy in the treatment of disease, affording an illustration of the good effects of pure air, and of its immense value as a prophylactic agent. Many of the cases admitted, indeed, recover merely by the use of a simple diet, and the change of air from the crowded steerage of the emigrant ship, to these well-ventilated and comfortable apartments.

Cases of yellow fever had been numerous during the autumn, as it appeared among the soldiers returning from the war in Mexico.

I saw the peculiar "vomit" of the disease, many specimens of which were preserved in sealed bottles; it was evidently sanguineous, and corresponded with the usual description of coffee grounds. This fearful malady is treated on general principles, it is regarded as fever of a typhoid type, and a very gentle and careful management succeeded best, the "*medicina perturbatrix*," being quite out of the question. It is frequently observed, that chronic dysentery is the sequela of yellow fever, and is best combated by the use of the nitrate of silver, on which more dependance is placed, than on the sulphate of copper.

On my second visit to the Quarantine Establishment, (December 4th,) I found some consternation excited by the presence of cholera; its introduction took place by the arrival of the packet ship *New York*, from Havre-de-grace. The history given by the Captain was, that after being at sea fourteen days, several of the passengers became sick, had diarrhœa, and in a few days some died; these cases were followed by others, showing more severe, and rapidly fatal, symptoms. Fifteen cases had been received into the hospital, of which seven had proved fatal: eight were under treatment, one of which, a child about eight years old, was very characteristic of the disease as we saw it in England in 1832,—the sunken eye, collapsed features, cold tongue, contraction of the abdominal muscles, and rice-coloured evacuations. The child was seized about fourteen hours before my visit; she died in four hours afterwards. Another case was that of a woman far advanced in pregnancy; she was seized with the usual symptoms, and died in twelve hours. The treatment adopted was the use of the hot-air apparatus, and frictions of the surface with tinctura capsici; calomel was administered internally, and I believe also opium, but here, as everywhere else, the awful rapidity of progress entirely counteracts the influence of ordinary remedies. In the cases which recovered the symptoms were milder, and thus afforded time for the successful exhibition of remedies.

The origin of cholera on board this emigrant ship would lead us to believe in the *spontaneous generation* of the disease, under peculiar circumstances. The passengers and crew left Havre all well; there was no cholera in the town. The number on board was upwards of 300, and they were badly provisioned, so that complaints had arisen among them about the food and water before any symptoms of disorder appeared. No systematic ventilation was practised, nor had the ship any surgeon, so that everything concurred to favour the appearance of disease.

It was remarked by the Captain, that at the time he first heard of any sickness among the people, (being off the coast of Nova Scotia,) the thermometer fell eighteen degrees within a few hours; how far this was a coincidence, or had any relation to the sudden appearance of diarrhœa, of course is matter of conjecture. The emigrants thus affected had not been in the hospital many days before several convalescents were attacked, and some died, with all the symptoms of cholera, so that the impression on the minds of the medical attendants was, that *under certain circumstances* the disease was *contagious*; the patients in the convalescent ward were separated entirely from the new patients, and I believe no farther propagation of the disease among them took place. It should be stated that these convalescents were all parties who were just recovering from gastric fever, and therefore would be peculiarly liable to such an attack.

My own impression is, that the poison of cholera may be propagated from one person to another under peculiar circumstances, but that, with ordinary precaution as to *cleanliness* and *ventilation*, we may generally prevent such a thing from occurring.

The appearance of the disease on board this emigrant ship shows how important is the appointment of a surgeon, as there is every reason to believe that in this instance the malignity of the disease was entirely owing to an accumulation of filth in the steerage of the vessel, and to the neglect of the early symptoms of sickness and diarrhœa.

Since I left New York the statement of the appearance of cholera in several of the transatlantic cities is confirmed, and I should fear, with the approach of warm weather, we may expect to hear of a serious return of the disease in a climate where gastric irritation is so common, and diseases of the mucous membranes always rife.

(To be continued.)

General Retrospect.

PHYSIOLOGY.

ON THE STRUCTURE OF THE PAPILLÆ OF THE TONGUE.

Mr. Hassall states that a minute and careful examination of the papillæ of the tongue has convinced him that the term conical, as applied to certain papillæ of that organ, is a misnomer, and that these are excavated and cupped in form.

Corresponding with this general shape of the papillæ, and determined by it, is the arrangement of the secondary papillæ, of a number of which each compound papilla is made up in a circle, the boundary of which corresponds with the raised margin of each cup.

The vessels and nerves supplying these papillæ of course follow a similar circular distribution.

In the recent state, and while the epithelium still remains attached to the subjacent structures, it is not easy to make out the true form of these cupped papillæ, in consequence of the number of filiform processes which are attached to them, obscuring it;

near the front of the tongue, however, and where these filamentary processes are either entirely absent or very short, the cupped form may be very readily determined, even while the epithelium is still adherent.

It is worthy of remark, that the processes in question, which are constituted of epithelium, follow the same circular arrangement which appertains to the papillæ and loops of blood-vessels and nerves; and also that they spring from the raised margins of the cups.

These observations are both interesting and important, because they disprove the opinion entertained by many physiologists and microscopists, that the filiform papillæ of the tongue have merely a mechanical office to perform, and that they are not concerned in any degree in the sense of taste, the form and arrangement of the several parts of each papilla showing an evident adaptation to the reception of gustatory impressions.

The filiform appendages entangle and delay the smaller particles of the food, and the cavities of the papillæ receive the nutritious juices, and retain it for a time sufficiently long to produce the necessary impression on the sensory papillæ by which each cup is encircled.

Considered altogether, it would be difficult to imagine or devise an arrangement of parts more admirably adapted to the purpose to be fulfilled.—*Lancet*, March.

ANIMAL CHEMISTRY.

DISCOVERY OF THE CONSTANT PRESENCE OF GRAPE-SUGAR IN THE WHITE OF EGGS.

Dr. Aldridge having been called on by the President, stated that he had to announce to the Academy the discovery by him of sugar, identical with the sugar of grapes, of honey, and of diabetes, being an essential constituent of the white of the egg of the common domestic fowl. In using the ordinary tests for the presence of this substance, the results will be found to be slightly modified, probably by the presence of other constituents. When white of egg is mixed with an equal bulk of potash water, and boiled, as in Moor's test, the liquid becomes of a deep amber colour; when the white of egg is mixed with some potash water, and then with hydrated oxide of copper, as in Capezzuoli's test, the latter dissolves, forming a fine pink solution, which, after some time, decomposes, throwing down a *brown* precipitate, probably on account of the presence of sulphurets. When the white of egg is mixed with potash water, and then a few drops of solution of sulphate of copper added, an intensely *red* coloured solution becomes formed, which, upon boiling, deposits a *brown* sediment.

But the cause of these reactions can be separated from the albumen of the white, and will then be found to present all the ordinary characters of grape sugar. To obtain this substance in a separate form, the whites of eggs are to be beat into a smooth pulp, with an equal bulk of rectified spirit of wine, specific gravity 850, and then heated; when approaching the boiling point of the spirit, the mixture will rather suddenly separate into a firm coagulum of albumen, and a straw-coloured spirituous liquid. The latter is to be strained off, and an additional quantity can be extracted from

the coagulum by strong impression. This liquid, which is highly alkaline, is then to be evaporated in a water bath, and during the evaporation transparent gelatinous-looking pellicles will be found to form, at first yellowish, but towards the termination, of a deep reddish brown, which are from time to time to be removed and preserved. Those pellicles are of an albuminous nature, becoming of a deep orange colour, when treated alternately with nitric acid and water of ammonia, although peculiar in being obtained by the evaporation of a spirituous liquid, from which no precipitate was capable of being thrown down by nitric or acetic acids. It is from these pellicles that the sugar is to be extracted, which can be done by triturating them with rectified spirit of wine, when they become whitish and opaque, then boiling and filtering. By evaporating the filtered liquid to the consistence of a syrup, and immersing in a freezing mixture, grains of grape-sugar will deposit on the sides and bottom of the vessel. These, as well as the syrup which yields them, have a taste at first intensely sweet, followed by a saline after-taste, from the presence of accompanying salts. They dissolve without discolouration in cold sulphuric acid, and behave in every respect similar to the sugar of diabetes.—*Medical Gazette*.

SURGERY.

SEVERE CHRONIC SCIATICA; INSTANTANEOUS CURE BY THE APPLICATION OF THE ACTUAL CAUTERY TO THE BACK OF THE FOOT: CHLOROFORM EXHIBITED.

By M. Robert.

A woman from the country, aged 50 years, of good constitution and naturally portly, had been tortured during the last fifteen months with severe sciatic pains in the right limbs as low down as the foot. These pains were so insupportable each night, that she was obliged to get up and walk about the room. During the day her sufferings abated a little. Various remedies had been used without success, especially blisters frequently repeated. On examination no change could be detected in the normal physical condition of the limb; the patient had become thin in consequence of the sleepless nights she had passed. M. Robert had her put under the influence of chloroform, and with a red hot iron made a good stripe along the outer part of the dorsal aspect of the foot, precisely in the direction of a line drawn from the external malleolus to the third and fourth toes. As soon as the patient came to herself she declared that the pain had completely left her. The following night she was perfectly calm and able to sleep for the first time; the pain has not returned at all since, and were it not for the suppurating wound upon the foot she might quit the hospital in a few days.

To-day, (fifteen days since the operation,) the cure of the sciatica has undergone no alteration, and she complains only of a slight smarting in the artificial wound. She will soon be able to leave the hospital, perfectly cured. This case ought to be added to the number of other parallel cases which we have previously reported as occurring in the practice of M. Robert. The treatment was first adopted by an Italian surgeon,

Petrini, who practised for many years at Naples under the name of Catugno, and being of great efficacy, is deserving the attention of practitioners.—*Annales de Thérapeutique*, Mars.

OBSTETRIC MEDICINE.

DR. SIMPSON'S AIR-TRACTOR.

[A paragraph having appeared in a former number of this Journal, being an abridged extract from the *Medical Gazette*, on the subject of the claim made by Dr. Mitchell, to the discovery of the air-tractor, we are requested by Dr. Simpson to insert the annexed letter to the Editor of the *Medical Gazette*.—Ed. J.]

To the Editor of the *Medical Gazette*.

Sir,—It certainly was neither my wish nor intention to join in the controversy relative to the air-tractor, which you have lately given in the pages of the *Gazette*. But as you have thought fit to write editorially on the matter, in your last number, and as your own remarks, and those of your correspondents, are, I think, calculated to do me unintentional injustice, I hope you will excuse me troubling you with one or two observations merely in my own personal defence.

1. In the *Gazette* for March 23rd, you published a short anonymous letter containing the following accusation:—"Dr. Simpson, of Edinburgh, lays claim to the merit of discovering the applicability of atmospheric pressure in aid of delivery." Now this accusation is totally groundless, because it is totally untrue. I never laid claim to any such merit. On the contrary, I have always given it to whom it is due,—viz., to Dr. Arnott. In the first published notice of the subject, I quoted in full Dr. Arnott's own words, in which he suggests the principles of the instrument. Could I do more? Let me add, that Dr. Arnott first published the suggestion in 1827; and at that time the editor of the *Medical Gazette* both derided the proposition and its originality.*

2. Dr. Mitchell sets out in the first sentence of his first letter to me, as given in your pages, with stating "I was rather surprised to find that you had not acknowledged me (Dr. Mitchell) as the discoverer of the application of the principle in such instrument." I have already stated that I gave the merit where I deemed the merit due,—viz., to Dr. Arnott; and I was not, till the last month, in the slightest degree aware that Dr. Mitchell had in any way attended to the subject, though I knew that other gentlemen had made attempts to reduce Dr. Arnott's suggestion to practice.†

* "We find the old sucking-horn of Hildanus brought into use for a most extraordinary purpose, being no less than to draw the child out of the womb. And we find a renewal of that most absurd idea, noticed in Pare's work, and so well ridiculed in Mr. John Bell's 'Principles of Surgery,' of applying a child's sucker to raise depressions of the fractured skull. Where is the limit to absurdity?"—*Medical Gazette*, vol. i. p. 219.

† As, for instance, Mr. Paul, one of the best pupils that attended my class during the same year as Dr. Mitchell. Mr. Paul proceeded in the matter much further than Dr. Mitchell. He did not, like Dr. Mitchell, merely write and theorise about an instrument, but tried to make one. Dr.

but without success. I feel certain that if Dr. Mitchell will only get an instrument constructed on his proposed plan (as given in the sketches he has sent me in his first letter,) he will find, I believe, that it is powerless and useless, and that it is not applicable in practice.

Let me add, that I am sure that no man can honestly accuse me, on any occasion, of ever failing, either in lecturing or in writing, to do every possible justice in my power to other investigators, and in distributing *sum cuique*, as far as my knowledge went.

3. In the first published notice of the air-tractor (see *Monthly Journal* for February, p. 556, and *Medical Gazette* for March 16, p. 480,) after mentioning the first case in which it was tried, in December last, I added that I "was not aware that any one had applied practically this obstetric means before it was employed in the case detailed. But the idea of using such a power had been long ago proposed by a gentleman for whose works and talents they all entertained the utmost respect,—Dr. Neil Arnott, of London. In his admirable word on Physics, Dr. Arnott alludes to the subject in the following words," &c.

In commenting upon this statement, Dr. Mitchell, in the *Gazette* (p. 531,) observes,—“He (Dr. Simpson) states that no one before himself, as far as he was aware, had made a practical application of Dr. Arnott's suggestion. The medical public (adds Dr. M.) will now see that he must have been perfectly well aware of its previous application by me.” Now, I still believe, that up to the time at which the above notice was published by me, no one had applied the aforesaid principle in practice. Dr. Mitchell avers he had applied it previously. If Dr. Mitchell will give the date of any case or cases in which he applied it, that date would settle the question; and I will at once yield the point if I am wrong.

4. In answer to Dr. Mitchell's first letter, I assured him that in the construction of the air-tractor I received no hint or suggestion “from his competition exercises, and that I never, as far as I knew, looked at these exercises, as the whole were entrusted to others to decide upon.” Allow me to add, that not only did I not read Dr. Mitchell's exercises, or those of the other competitors (four of whom were awarded with prizes,) but up to the date of his letter to me I never heard, from himself or from any other person, the most distant hint of any ideas of his about the construction of an air-tractor.

On asking Dr. Duncan, who read the exercises over, he assures me that from the time of his looking over the papers till I showed him Dr. Mitchell's letter, he had no remembrance whatever of Dr. Mitchell alluding to the subject; and his observations on it, let me add, must, I think, have been most entirely out of place in such exercises, as none of the twelve questions given out, referred at all to instrumental delivery. If Dr.

Mitchell alludes to my suggesting the investigation, as a fit subject for the ingenuity of my pupils, in 1847-48. When lecturing, I have always been constantly in the habit of directing specially the attention of my pupils from time to time to subjects open for new inquiry, and tried to stimulate them to think on such matters for themselves, write their theses on them, &c.

Duncan did not attend to such a subject thus irrelevantly introduced into the exercises, and in which subjects he (Dr. Duncan) was in no respect interested, I do opine he was in no degree to blame, as you seem to think he was.*

5. In my note to Dr. Mitchell (see *Gazette*, p. 520,) I stated that "I had thought and talked often of making an air-tractor, such as I have latterly constructed, long before you were my pupil."

Dr. Mitchell affects to doubt this. I have mentioned Dr. Arnott's suggestion and the subject publicly, at more or less length, every year in lecturing, since I commenced teaching midwifery, ten years ago. It very seldom does happen that a subject of mere medical conversation happens to be a subject of actual record; but in this case it oddly and fortunately enough happens that it is so. In February, 1848, six or eight weeks before Dr. Mitchell's prize exercises were written in my class-rooms, Dr. Clay, of Manchester, was called down professionally to Edinburgh, to perform the operation of ovariectomy. In his *Obstetric Journal* for 1st February last, Dr. Clay, in speaking of the air-tractor, the utility of which he doubts, observes:—"The instrument is not new to us, having conversed with Dr. Simpson a year ago on the subject."—p. 60.† At last, in December, 1848, I was induced to set about the construction of a proper instrument in consequence of witnessing, in the Royal Infirmary here, some trials with the artificial French leech; and at first I thought that an exhausting cylinder and piston, on the same principle, would answer best. In pursuing the investigation after it was once begun, I had to make innumerable trials with, and changes on, the instrument before I obtained a form practically and really useful.

6. Dr. Mitchell purports to report correctly, to you and to your readers, various circumstances relative to my statements in lecturing and awarding the prizes, &c.; and founds various conclusions upon his own memory for his own argument. Dr. Mitchell says, that in my lectures I stated that I had "attempted in vain, at the Edinburgh Maternity Hospital, to apply a leather sucker to a child's head." I did not state anything of the kind, because I never made any such attempt. I never tried till last December to apply the principle in actual practice.

Lastly. Permit me to observe again, that we are indebted to Dr. Arnott for first suggesting the "applicability of atmospheric pressure in aid of delivery;" and

if I have any claim to any merit in the matter, it is this,—that after Dr. Arnott's idea had lain dormant and useless for twenty years, I reduced Dr. Arnott's suggestion to actual practice,—was the first to construct a useful and applicable air-tractor,—the first to use such an instrument in practice,—and the first to point out the cases fit for its use. Further, in the construction of the air-tractor, I was indebted to no one but Dr. Arnott, in even the remotest degree, for any hint or aid whatever. I may be, perhaps, excused for adding, that I have now employed it repeatedly, both in cephalic and pelvic presentations, and both when the head was still high above the brim, and already sunk into the pelvic cavity; and I believe that the construction of the air-tractor is still very far from being so perfect as it will yet be rendered.

Yours, &c.,

J. Y. SIMPSON.

Edinburgh, April 7, 1849.

TOXICOLOGY.

RECOVERY FROM THE EFFECTS OF A LARGE DOSE OF DIGITALIS.

By M. de Colleville.

A woman, aged 68, while suffering from œdema of the lungs, and when nearly convalescent, was ordered to take an infusion of the dried leaves of digitalis, in the proportion of (60 centigrammes) $9\frac{1}{2}$ grains in a quart of water. The druggist by some accident used (15 grammes) $231\frac{1}{2}$ grains. This was infused in eight glasses of water, and administered to the patient in divided doses. She was soon attacked with great uneasiness, nausea, bilious vomiting, confused vision, amounting to blindness, ringing in the ears, vertigo, convulsions, and syncope. The face was pale; there was great coldness of the skin, with palpitation; thready slow, and intermittent pulse, and pain in the abdomen. The effects were produced by four doses of the infusion. A physician who saw the patient the following morning found her in a highly dangerous condition. He prescribed saline enemata, sinapisms with warm bottles to the feet, and frictions with camphorated spirit to the skin. Strong coffee was administered internally. In six hours there was no apparent amendment: the vomiting, convulsions, and fits of syncope continued, but the difficulty of breathing under which the patient had previously laboured had entirely disappeared; there were no longer symptoms of œdema of the lungs, and the chief object then was to counteract the effects of the poison. Syrup of orange-peel and other simple medicines were prescribed, and an enema of assaœtida and camphor administered. Three days after the accident the vomitings were less frequent, and the syncope and convulsions had ceased, but there was still vertigo, with ringing in the ears, and hallucinations of vision. In six days the patient had perfectly recovered from the effects of the poison.—*Journ. de Méd. de Bordeaux*.

* Of course we do not blame Dr. Duncan for want of memory. As Dr. Duncan decided against Dr. Mitchell, he must have read his papers; and we confess that it appeared extraordinary to us, that although no long time had elapsed, he did not recollect that a description of an air-tractor had been given in one of the exercises, when public notice was so strongly called to the invention by Dr. Simpson. It is evident, however, from Dr. Simpson's statement, that he, Dr. Simpson, knew nothing of the contents or relative merits of the papers, and that Dr. Duncan had wholly forgotten this reference to the air-tractor.—*Ed. Gaz.*

† Dr. Simpson has forwarded to us a letter from Dr. Paterson, by which it appears that so long back as the year 1836 the subject of the air-tractor had been discussed by them.—*Ed. Gaz.*

ILLICIT PRACTICE OF DRUGGISTS.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND
SURGICAL JOURNAL.

SIR,

On perusing your Journal of to-day, I there see to my great satisfaction, your attention directed, by a constant reader, to the illicit practice of druggists. Alas! what an odium on our should-be-liberal profession. Whom have we to blame for this great outrage on society and injustice to ourselves but the very heads, I am truly sorry to say, of our profession,—physicians and those in extensive practice acting as such, who are, perchance, too busily engaged to compound their own medicines, or consider it degrading and not sufficiently genteel to do so.

In my opinion, if ever the medical profession is to be what it ought, we should have a *full and constant* exposure of all its abuses for the general good of its members; and in consideration of a general good, a ready foregoing of all selfishness and individual interests; the physician, openly and firmly co-operating with the surgeon-apothecary and apothecary, instead of, I fear, as is too frequently done, sacrificing both his principle and his best feelings, as well as in very many instances, the welfare of his patient, to a mutual understanding with the mere druggist, who is generally self confident and presuming in proportion to his support and ignorance. How disgraceful such conduct! What we want is individual reform, and until this is accomplished, an entire and unreserved exposure of all abuses and inconsistencies. I should suggest that physicians and those not dispensing their own medicines, should forthwith convene meetings and enter into proper measures and arrangements for the purpose of preventing prescriptions, as far as could be done, from falling into the hands of druggists or illegal compounders, and I am persuaded more real and intrinsic good from this will redound both to the public and to the profession than any other measure which could be adopted. There is, it is much to be feared, no disease in this country incident to man, more destructive than the interference of druggists and quacks; and any physician conniving at a druggist and furthering his views by supplying him with prescriptions for use, ought to be publicly exposed.

I am, Sir,

Yours very respectfully,

A MEMBER OF THE PROFESSION.

April 18, 1849.

N.B. I shall feel obliged by your giving insertion to the above.

SURREPTITIOUS PUBLICATION.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND
SURGICAL JOURNAL.

SIR,

My attention has been called to a small pamphlet purporting to be a reprint of a paper of mine, which was published some weeks ago.

The pamphlet has been circulated amongst many members of the profession. It is not at all a true copy of my paper, and is evidently printed to obtain some object, the nature of which I am at a loss to

comprehend. It is stated to be published by a firm not in existence, as I have ascertained, and has no printer's name attached to it.

It is scarcely necessary for me to state that I knew nothing of the pamphlet until it was shown to me late last night by a friend.

If you will do me the favour to insert this note in your next Journal, I shall feel particularly obliged to you.

I am, Sir, yours faithfully,

G. T. GREAM.

42, Hertford Street, London.

May 9, 1849.

EXTRAORDINARY BIRTH.

On Monday, April 9th, 1849, I was summoned hastily at a quarter past seven o'clock, p.m., to attend Mrs. D. in labour, the wife of a respectable shopkeeper in this town. She is 35 years of age, well-formed, and rather corpulent. Has had two children before, one aged seven years the other five, both living. The husband is a strong active man.

Mrs. D. had attended a funeral on the afternoon of the above date, and was taking tea with the party, a few doors from her own house, when labour commenced. She went home, walked up-stairs, and pains coming on in rapid succession, the child was born at half-past seven p.m. At this time she was alone, but her cries brought assistance. A neighbour divided the cord, and carried the child down stairs to the kitchen fire, not having yet noticed anything unusual. The child cried lustily.

On my arrival, which was immediately after the separation of the child, I proceeded to extract the placenta, and was then called down stairs in a most mysterious way,—concern and amazement being depicted in the messenger's countenance. On examination of the child, (a male,) I found it possessed neither upper nor lower extremities, but in place of them, four short stumps between two and three inches long, and closely resembling the ordinary stumps after amputation. The head, chest, and abdomen were fully formed, the genitals also. The anus was small and contracted, but a director passed readily into the bowel, and the child had already voided meconium into the wrapper. On passing the finger along the median line of the sacrum a projection or spicula of bone was to be felt, giving the impression that the lower posterior arches of the sacral canal were not complete. The two central incisors of the upper and lower jaw are quite distinguishable and prominent in the gum.

Friday, April 13th. I have this day seen the child. It is well, and takes nourishment. I obtained the following measurements:—

BODY.

Inches.

- | | |
|---|------------------|
| 1. Entire length of body from vertex to nates | 12 |
| 2. Round chest under axilla | 11 $\frac{1}{2}$ |
| 3. Round abdomen | 11 |

HEAD.

- | | | |
|--|-----|--|
| 1. From nasal to occipital protuberance .. | 6½ | |
| 2. From ear to ear across vertex | 7½ | |
| 3. Circumference of head above the ears, viz.,
from ear to ear across frontal bone 8½ in.;
continued across occipital bone 5 in. | 13½ | |

EXTREMITIES.

- | | |
|---|---|
| 1. Stumps of two upper extremities equal .. | 3 |
| 2. Stump of right lower extremity | 2 |
| 3. Stump of left lower extremity | 3 |

I certify that the above is a correct statement.

FRED. SMITH GARLICK, Surgeon.

5, Cheapside, Halifax.

Medical Intelligence.

ROYAL COLLEGE OF SURGEONS.

Gentlemen admitted Members on Friday, April 27th, 1849:—R. E. Rusher; F. J. Earle; C. N. Foote; T. B. Phillips; J. W. Saunders; T. S. Rowe; J. W. Smith; C. Welch; J. H. Lakin.

Gentlemen admitted Members on Friday, May 4th:—George Gwynn Brown, Stourport; William Clapham Cantley, Hedon, near Hull; Robert Charles Hurst, Bedford; James Lorcan Kennedy, London; Charles Lowdell, Lingfield, Surrey; John Jones Merriman, Kensington; William Ferdinand Wratisslaw, Rugby, Warwickshire.

SOCIETY OF APOTHECARIES.

Gentlemen admitted Licentiates on Thursday, April 26th, 1849:—John Candler, Walpole, Suffolk; George Hatt Cook, Tetbury, Gloucestershire; William Evans, (as assistant,) Glamorganshire; John Gaman, Hambleton, Hants; Robert Coane Roberts Jordan, Teignmouth; William Annable Skinner, Headcorn, Kent; William Palmer Steele, Abergavenny; William Henry Tinney; Ottery St. Mary, Devon; John William Trotter, Durham; Thomas Henry Waterworth, London; Henry Wellings, Royal Navy; John Horseley White, Wolverhampton; John Wood, Bradford, Yorkshire.

Admitted Licentiates on Thursday, May 3rd:—George Down, Pimlico; George Anthony, Kirsopp Lake, Devonshire; Thomas Mudge, Bodmin, Cornwall; Daniel Rossiter, Frome, Somerset.

OBITUARY.

Died, May 3rd, at Brighton, in the 67th year of his age, Joseph John West, M.D.

May 5th, at Feckenham, Worcestershire, Edward P. Turner, Esq., Surgeon, aged 31.

May 10th, at Worcester, after three months serious indisposition, Robert James Nicholl Streeten, M.D., Secretary to the Provincial Medical and Surgical Association, and Editor of this Journal.

PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION.

ANNIVERSARY MEETING.

The programme of the approaching Anniversary will be advertised, as usual, in the following number of the Journal. It will be held at Worcester, on Wednesday, August 1st, and Thursday, August 2nd, under the Presidency of Charles Hastings, M.D., F.G.S.

The "Addresses in Medicine" and "Physiology" will be read respectively by Dr. C. W. Bell, of Manchester, and Dr. Sibson, of London, late of Nottingham.

Communications usually addressed to the Secretary, to be forwarded to J. P. Sheppard, Esq., Foregate Street, Worcester.

NOTICE TO MEMBERS.

Gentlemen who have not yet paid their subscription for the current year, or who are in arrears, are requested immediately to forward the amount due to the Treasurer of the Association, as the accounts are now about to be made up for the Annual Meeting.

CHARLES HASTINGS, M.D., F.G.S.,
Treasurer.

TO CORRESPONDENTS.

Communications have been received from Mr. Leach; Æsculapius; Dr. Butler Lane; Diogenes; Dr. Buller; Dr. Ballard.

We have received a communication from Mr. Skevington of Ashbourne, Derbyshire, with a notice of an inquest on Henry Vernon, of Brailsford, in the same county, who died from injuries received in a public-house brawl. It appears that Mr. Skevington, who did not see the deceased during life, attended the inquest and was subsequently refused a fee by the Coroner. He was neither examined nor summoned in the official manner, although informed by the father that he would be wanted. Under these circumstances we cannot see that there is any blame attached to any party, for although Mr. Skevington may naturally enough feel annoyed at his loss of time, still the error arose from his attending to the request of the father of the deceased, without waiting for an order from the coroner himself. We believe it is almost universally the custom for the coroner to select the medical opinion, when, as in the case before us, there had been no medical attendance during life.

In consequence of the lamented death of Dr. Streeten, it is requested that all letters and communications be sent to J. H. Walsh, Esq., Foregate Street, Worcester. Parcels and books for review may be addressed to the care of Mr. Churchill, Princes Street, Soho.

PROVINCIAL MEDICAL & SURGICAL JOURNAL.

A COURSE OF LECTURES ON SURGERY,

DELIVERED IN THE

MEDICAL SCHOOL OF CAMBRIDGE.

By GEORGE MURRAY HUMPHRY, Esq., Downing
College, Surgeon to Addenbrooke's Hospital.

LECTURE VIII.

EFFECTS OF INFLAMMATION ON THE TISSUES: ULCERATION.

Atrophy from Inflammation, probably in part dependent directly on the Inflammatory Process, though seldom entirely so: Softening, sometimes the only evidence of Inflammation discoverable after death,—not the mere result of œdema, or of impaired nutrition, but a direct effect of Inflammation; Softening from other causes. Cases in which Softening from Inflammation most quickly occurs; Chronic softening, Yielding of Bones, Ligaments, &c.; Interstitial Absorption witnessed in Bones and Cartilages.—Ulceration, nature of the process; its difference from Suppuration; Healing by Granulation, Cicatrization, and Contraction; advantages and disadvantages of the latter; Peculiarity of Ulcers in the Cornea, and in Cartilage; Classification of Ulcers into Inflammatory, Phagedenic, and Atonic; Inflammatory Ulcers, proportionate in their progress to the Accompanying Inflammation; may be Acute or Chronic; Acute Ulcers; Chronic Ulcers; causes of their frequent occurrence in the Skin of the Legs, their General Characters and Treatment; their frequent Relation to Disordered state of Constitution; Ulcers under Thickened Cuticle.

The destructive effects of inflammation are most quickly produced, and are most marked in those tissues which are endued with the greatest vascularity and delicacy of structure, such as the nervous centres, the internal organs, mucous membranes and the skin; and, secondly, in those tissues whose vitality is naturally low, such as the fibrous membranes and bone, or whose nutritive and reparative energies have been reduced by some former disease or accident. They are most marked in corresponding ages and habits of body, that is to say, in infants, and persons of excessive fineness and delicacy of physical formation on the one hand, and in the aged, the debilitated, or the infirm on the other. They consist of atrophy, softening, interstitial absorption, ulceration, and mortification.

The first of these, atrophy, we cannot often distinctly attribute to the direct and unassisted agency of inflammation; for inflammation is so commonly associated with suspension of function, and so quickly produces other alterations of structure, which in their turn affect the nutrition of the part, that we are generally obliged to refer to a combination of causes the atrophy attendant upon the inflammatory process. Thus, atrophy of the eyeball sometimes follows deep seated inflammation of the organ, but it takes place only when the internal tunics of the eye have been so changed as to destroy vision. The wasting of the testicle, occasionally resulting from hernia humoralis and other inflammatory affections, is probably always associated with an impervious condition of the vas deferens, or of the tubes of the epididymis and rete testis; and a shrunken state of a liver or kidney which has been long subject to inflammation, seems to result in great measure from the pressure exerted upon the structure of the organ by the contracting lymph effused into its substance, or deposited on its exterior. Indeed, the atrophy consequent on inflammation is so generally associated with some other structural change or variation of function, which may be regarded as the direct cause of it, that I can scarcely adduce to you a fair instance of inflammatory atrophy strictly so called, unless we reckon as such some of the cases presently to be mentioned, in which interstitial absorption has taken place in inflamed cartilages and bones. Nevertheless, it is probable that atrophy from suspension of function, effusion of lymph, and other causes, takes place most rapidly when the organ affected is or has been the seat of inflammation; and we may remark, that wasting of the eyeball does not follow the loss of vision occasioned by opacity of the cornea, unless the deeper tissues of the eye have been inflamed. Moreover, diminution of size, and imperfection of structure, are such frequent results of inflammation, and are so closely connected with it that we can scarcely fail to admit, though it may not be easy to prove it unequivocally, that an impairment of nutrition, or atrophy, is one of the effects directly resulting from that modification of the nutritive processes which constitutes inflammation.

The first perceptible change which usually occurs in the texture of an inflamed part is owing to a diminution of the cohesive force of attraction between its component particles, and consists in a loosening or softening of its structure, so that it rends easily, and gives way under slight pressure of the fingers. We have frequent

opportunities of observing this change in the delicate internal organs when they have been the seat of inflammation, and sometimes it affords the only means of deciding the nature of the disease which has been going on during life. The other phenomena of inflammation may have passed away; the congested state of the vessels often subsides in the last hours of life, or, if congestion be found, we cannot always rely upon it as an evidence of inflammation, because it may have been occasioned by mechanical causes operating after death. But a softened condition of an organ, provided decomposition has not commenced, is a pretty sure sign that an inflammatory change has been going on. Some time ago, I examined the body of a lady who had died after a brief, but severe illness, during which, the prominent symptoms had been fever, with pain in the right hypochondrium, and the only trace of disease I could find was a softened condition of one part of the liver. Nearly one half of the organ was reduced almost to a diffuent pulp. There was no change of colour; no lymph or pus to be discovered; merely a softened state of the texture of the gland, and had it not been for this softening, it would have been impossible to discover the nature, or even the seat of the disease.

The state of softening is usually accompanied by the effusion of a preternatural quantity of serum, or some other product of inflammation, which, separating the fibres of the part affected, increases the softening, or rather, renders it more apparent. It must not on that account be supposed that softening depends merely upon the presence of an unusual quantity of fluid; for if it did, simple oedema would be sufficient to cause it. Something more than a mere variation in the amount of the fluid which moistens the tissue of an organ is necessary to occasion its softening. The imperfection or suspension of nutrition consequent on inflammation may in part account for it, especially in vascular and highly organized structures where the mutation of particles is rapid; but this is scarcely sufficient to explain the softening which is not uncommonly found in the harder organs, the bones, cartilages, and ligaments, where the function is of a passive nature, and the processes of waste and repair go on but slowly. There must be some other cause in operation to effect this change in the inflamed part, besides the presence of a preternatural quantity of fluid in its interstices, or the suspension of its function. There is, probably, in addition to these, some alteration in the vital and physical properties of the textures, directly resulting from, or associated with the inflammatory process, of a kind similar to that which, in the more severe stages of inflammation, gives rise to ulceration and mortification.

That softening of some organs, more particularly of the brain, may result from impaired nutrition, is shown by the cases in which it has been occasioned by a deficiency in the supply of blood. Thus, softening of one hemisphere of the brain is no uncommon sequence of a ligature of one carotid artery, and we lately examined a case in which softening of the medulla oblongata was attributable to the obstruction

of one vertebral artery at the point where it enters the cranial cavity, the other vertebral having been rendered impervious near its origin by disease at a former period. The paralysis of old people sometimes depends upon softening of a part of the brain, with a diseased condition of the arteries leading to it. It is well to bear in mind, also, that softening of the nervous centres may be occasioned by mechanical injury, and may closely resemble the softening which proceeds from inflammation or impaired nutrition. Indeed, it is often not possible to decide from which of these three causes (inflammation, impaired nutrition, or mechanical injury,) the softening of a brain or spinal cord proceeds.

In many persons who have passed the middle period of life, the textures become soft and flaccid. They yield easily to slight mechanical forces, so that a gentle blow will occasion a severe bruise. The heart's action becomes feeble, its walls thin and flaccid, perhaps fatty, and the pulse is irregular and unequal, sometimes intermitting. Such persons bear the remedies usually employed to combat inflammation, very indifferently; they are easily prostrated, and the effect of the disease in producing softening and destruction of the tissues is especially remarkable in them. The lady in whom the softening of the liver occurred, to which I just alluded, was of this temperament; she had indulged freely in the pleasures of the table, had been bled rather largely at the commencement of the attack, and all the organs were remarkable for the looseness of their texture and the ease with which they could be torn. I need not say that in other cases where there is a predisposition to softening from deficient supply of blood, or from mechanical injury, a slight degree of inflammation will be sufficient quickly to induce it.

We have frequent opportunities of observing another effect of softening when it takes place more slowly under the influence of chronic inflammation affecting the harder parts of the frame, in consequence of which they become weakened and rendered unfit for their mechanical functions. The bones, long subject to chronic inflammation, may bend beneath the weight of the body or under the pressure of surrounding muscles. Here are specimens of bones which have yielded in this manner. You observe in this tibia a sudden bend at the part where there is thickening, some ulceration, and other evidences of inflammation. This is a different disease from rickets, which generally affects the whole skeleton in a greater or less degree, and depends rather upon imperfection of the developmental processes, than upon disease occurring subsequently. In rickets, the bones do not acquire their proper strength with a rapidity proportionate to the growth of the rest of the frame, and therefore yield under the increasing weight of the body; but the affection we are now considering is due to the softening effects of inflammation operating, it may be, upon bones which have attained their full strength and size.

The ligaments suffer in the same manner as the bones, and when they have been for some time inflamed lose their tension and force of resistance. Hence, in some measure arises the looseness and sensation of weakness so often experienced in chronic inflammatory

affections of these parts. The relaxation and lengthening of ligaments thus weakened sometimes proceeds to such an extent, that they yield to the constant traction exerted upon them by the surrounding muscles or the weight of the limb, and may permit actual dislocation of a joint to take place. Here are specimens in which dislocation of the knee has ensued in the course of long-continued disease of the joint; the ligaments are all entire, but they have yielded so as to permit displacement to the extent you see. There are in the museum of St. Bartholomew's Hospital, some interesting specimens of lengthening of the capsule of the hip-joint, in one instance to such an extent, that the head of the thigh bone having escaped from the acetabulum rests upon the dorsum of the ilium. Some time ago there was a lad in this hospital in whom the same lengthening of the capsule of the joint appeared to have taken place during inflammation, for, though he was able to bear some weight upon the limb, the head of the thigh bone slipped in and out of the acetabulum. It occasioned him no pain and he rather enjoyed the exhibition of his new feat. We took a good deal of pains to provide an apparatus which should prevent the displacement when he walked, but I am not confident that we succeeded at last, and I have for some time lost sight of the boy. You may have observed, that in inflammation of the wrist joint, the muscles and tendons ceasing to brace the joint, and the ligaments becoming softened by the inflammation and yielding to the weight of the hand, which is usually kept in the prone position, the carpus, after a time sinks upon the pillow, and leaves the lower ends of the radius and ulna prominent on the dorsal aspect of the limb. This relaxation of the ligaments and consequent displacement of the articular surfaces in cases of severe and long-continued disease of a joint, is no infrequent event, and unless you were acquainted with the real nature of the change you might imagine that ulceration or destruction of the ligaments had taken place. Surgeons who are not in the habit of dissecting these cases often assert that the ligaments of a joint are gone, but you will generally find upon examination, even where very great displacement has taken place, that the ligaments though stretched are entire. I speak more particularly of the knee and wrist joints, for in the other instance in which much displacement occurs in the course of disease,—viz., the hip, the capsule of the joint is usually ulcerated through before the head of the thigh bone and escapes from the acetabulum.

The staphylomatous bulgings of the cornea and sclerotic occasionally following long-continued inflammation of those tunics, are in like manner due to this softening influence of the disease, which weakens and renders them unable to support the pressure of the aqueous and vitreous humours.

Another effect of inflammation is interstitial absorption, which is nearly allied to softening, and occupies an intermediate position between it and ulceration. By this process the parts covering an abscess and intervening between it and the surface are removed, as I before explained to you; and the rapidity with which

an abscess advances to the surface, is proportionate to the acuteness of the attendant inflammation. The effects of interstitial absorption are most evident in the bones, because in consequence of the hardness of their texture, the vacancies occasioned by it do not so easily escape observation. Thus we often find bones becoming preternaturally porous under inflammation, and sometimes they are rendered so delicate as well as soft, that a scalpel may be passed through them without turning its edge. In this specimen of an inflamed thigh bone the cancellous texture has been entirely removed from the interior of the shaft, and the same change is commonly found to have occurred in the sequestra of necrosis. In the bones lying on the table, the outer compact walls of the shafts have been rendered porous and rough, so as to look as if they had been worm eaten; and the new bony deposit which has taken place on their circumference has been run into some of these holes and crevices while it was in a soft and fluid state, and solidifying there, has acquired a firm connection with the old bone. The reunion of broken bones is in like manner effected by a slight degree of inflammation, followed by interstitial absorption and roughening of the fractured ends, at the same time that a new cementing material or callus is poured in between and around the surfaces thus prepared for it. The cement is in this manner intimately blended with each of the broken ends, and concreting or ossifying, forms a firm bond of union between them. The transverse connecting rivets uniting the laminae of an inflamed bone may also be absorbed, and the laminae themselves may be separated from one another by the effusion of serum or lymph between them. These interposed products becoming afterwards ossified occasion induration and permanent thickening of the bone.

The interstitial absorption, consequent on inflammation, may also occasion the removal of the cartilages, and may alter the shape of the articular ends of bones. The gradual destruction of cartilages and the strange distortions which the hip and other joints undergo in the course of chronic rheumatism are remarkable examples of this. Recent lymph formations are particularly liable to this effect of inflammation, and so are parts already predisposed to interstitial absorption by a deficient supply of blood or a failure of the nutritive powers, such as the bones of old people. I am at this time attending a man, aged 86, whose humerus snapped in the middle as he laid old of a friend to help him to walk up stairs. For some weeks previously he had complained of pain in this part of the arm, and it is probable that some slight inflammatory attack, weakening and causing absorption of the bone, was the immediate cause of the accident.*

If the same influence which engenders softening

* This old man is since dead. The humerus was light, porous, and fragile; no attempt at reparation had taken place; the broken ends were rough and worm eaten on the surface for some distance above and below the fracture. This condition of the ends of the bone was probably due to the inflammation consequent on the injury, which was soon followed by its destructive results, but failed altogether to induce any reparative effects.

and interstitial absorption be exerted in a severer form it will, on a surface, occasion an actual breach or solution of continuity—in other words, it will give rise to an ulcer. The process of ulceration consists in the diminution of the cohesive force of the tissues at the part affected, to such an extent that they are disintegrated, and particle after particle becoming detached, pass off with the serous ingredients of the blood effused among them and constitute the discharge. Some of the atoms of the ulcerating tissues are, no doubt, returned into the circulating current in the same manner as in interstitial absorption, but a considerable quantity of dissevered fragments escape with the discharge, and beneath the dirty serous fluid which moistens a spreading ulcer, may be seen a thin layer of greyish or dark, or otherwise discoloured tissue in process of disorganization. We may, therefore, regard ulceration as the progressive or atomic death of a tissue occasioned by inflammation. It is not dependent simply on the arrest of nutrition, but it is the result of some destructive influence directly resulting from the inflammatory process, whereby a premature dissolution and disintegration of tissue is engendered.

You will perceive that ulceration does not depend any more than nutrition upon a peculiar action of the vessels of the part; it may take place in the same manner as the other effects of inflammation, in textures which are scantily supplied with vessels, or entirely devoid of them,—for instance, in cartilage, and in the cornea; neither is it the result of the erosive influence of a particular fluid, generated by the inflammatory process, for there is no evidence of the existence of any such fluid; it consists merely in the molecular death and separation of the components of the structure, in consequence of some direct influence on their vitality exerted by inflammation. Hence it follows that parts which, in consequence of the feeble state of their vital powers, can least resist the disturbing influence of inflammation, are most prone to fall into ulceration, and we are thus able to explain the frequent occurrence of ulcers, in feeble and emaciated persons, on the lower extremities, and on parts which have been weakened by injury or disease.

The processes of suppuration and ulceration are evidently very different, inasmuch as the former depends upon a change being wrought in the particles of the blood effused among the tissues, of such a nature that they cohere together into little masses called pus-globules, which have no ability to undergo any further organization, and therefore act as foreign bodies; whereas ulceration consists in the premature death and separation of the molecules of the tissues, whereby a solution of continuity is effected. Though suppuration very commonly follows ulceration, the two seldom proceed together at the same spot, so seldom, indeed, that the formation of pus is a pretty sure sign that an ulcer has ceased to spread. The cases in which an ulcer heals in one direction, and spreads in another, do not constitute an exception to this statement, because even in them ulceration and suppuration do not go on together at the same part of the ulcer.

So long as an ulcer continues to increase its margin

is sinuous and uneven, and its surface is foul, ragged, and covered with the disorganized remains of dead and decomposing tissues, fragments of which, mixed with the serum, constitute the discharge. The first sign of improvement, and of the cessation of the ulceration, is a [diminution of this foul dirty covering,—a cleaning of the ulcer as it is called. The exposed surface of the ulcer becomes red, and some pus-globules are intermixed with the discharge. The reparative processes next commence with the formation of granulations over the surface of the ulcer. These are composed of lymph, organized and vascular; they form at the bottom and sides of the ulcer, fill up its cavity, and reach, or even sprout, beyond the level of the surrounding skin; at the same time the margin of the ulcer which had previously been jagged, becomes even, and the size of the ulcer begins to be diminished by the contraction of the granulation structure forming on its surface. This latter change takes place in accordance with that contractile property of lymph which I have so frequently alluded to.

The granulations are of pointed and conical shape, and being set closely together at their bases, they give to the surface of the ulcer an uneven granular appearance. As soon as they have reached the level of the skin, and sometimes before, the granulations which are in immediate contact with the skin become gradually converted into a structure called cicatrix, having a resemblance to the cutis, and bearing a cuticle upon its surface; it seems as though a fine, delicate, reddish pellicle were projected from the skin over the granulations, and this pellicle gradually advances towards the middle of the ulcer, till at length the whole is covered by it, or healed.

While the surface of the ulcer is thus closed in by cicatrix, its size continues to be diminished by the contraction of the healing medium, and this property of contraction exists in the cicatrix no less than in the granulations that precede it. It is by the combined influence, therefore, of these two forces, contraction and cicatrization, that an ulcer is healed. The share which each of them has in the cure varies according to circumstances. Where the surrounding textures are loose and unadherent, the ulcer is quickly diminished by the contraction of its granulations, and the cicatrix is small in proportion to the size of the gap which has been closed. Where, on the contrary, the surrounding textures are tough and resisting, or the skin fixed to the parts beneath by adhesions or other cause, contraction can take place to a less extent; the healing must be in greater measure effected by cicatrization, and is proportionately slow. The closure of the last or middle part of a large ulcer is always very tedious; partly because contraction has taken place nearly to its full extent, and can offer but little further assistance towards the completion of the cure, and partly because the reparative work of cicatrization is languidly accomplished in proportion to the distance from the point at which it commenced. It has been already remarked that the fibrin of delicate and scrofulous persons, though deficient in contractile power, quickly admits of organization, and you may have observed how little

the ulcers of these persons are closed by contraction, but that, nevertheless, they sometimes skin over very rapidly—in an imperfect and unsound manner, I grant—for the cicatrices thus quickly formed are large, weak, and very liable to ulcerate again.

The new medium by which an ulcer is closed is always inferior in vital, as well as in physical, qualities, to the texture whose place it occupies. The contraction of an ulcer has, therefore, this very important advantage, that by diminishing the gap it renders a smaller surface of the new medium requisite. Some comparatively slight disadvantages, it is true, result from it, such as the formation of strictures, the unsightly puckering of integuments, and even the distortion of limbs. These evil consequences are, however, only occasional, and are not sufficiently frequent to counter balance those good effects of contraction, the influence of which is universal. The disposition to contract often continues for a considerable period after the complete healing of the ulcer, but it diminishes gradually, and altogether ceases after a time, when the cicatrix becomes soft, supple, and paler even than the surrounding skin.

The indisposition of parts to heal is, no less than their liability to ulcerate, proportionate to the feeble state of their vital energies; hence the difficulty of curing ulcers on the lower extremities of old people, and on limbs, where, in consequence of a varicose condition of the veins, the circulation is sluggishly conducted. Hence, too, the ulcers occurring on a limb which has been weakened by disease or injury are very troublesome, and the sores occasioned by unequal pressure upon a broken limb are often particularly so; for a limb which has been so severely injured, and has been, in addition, kept for some time in a constrained position, is long in recovering its natural force of nutrition, as well as its proper physical powers. Your recollection will supply numerous instances of the slow healing of ulcers under similar circumstances, such as the bed-sores, occurring in emaciated persons, and the ulcers on paralysed limbs. We fear to make incisions into the œdematous legs of the dropsical patient, because we know that tedious ulcers, if not mortification, are likely to be the result of such meddlesome surgery.

The cornea, and the cartilages covering the articular ends of bones, differ from most other tissues in the density and toughness of their structure, and more particularly in being in their natural state destitute of blood-vessels. Each of these tissues is also subject to a peculiar kind of ulceration. The acute ulcer of the cornea corresponds with ulcers in other parts. It has a flocculent grey surface, and the clearing of the dirty opaque coating from the ulcer is a sign that the disease has been arrested. But the peculiar ulcer of the cornea to which I wish to direct your attention is of slow formation, not attended with much inflammation, and quite clear and transparent, so that it is very likely to escape observation. A child is brought to you who is observed to avoid the light, perhaps to cry at times with pain in one eye, which waters, and is kept partially closed. You notice some redness of the conjunctiva, and finding no other disease upon a slight inspection,

regard the case as of little importance. No improvement being derived from your prescriptions, you are induced to examine the eye more carefully, when you discover a slight inequality in the surface of the cornea; it looks as if a thin slice had been planed off at one part, or there may be a little indentation as if a small semicircular piece had been chiselled out with a sharp instrument. Such ulcers are of common occurrence, though they often escape observation. They continue sometimes for a considerable period, penetrating deeply into the cornea, and resisting the ordinary remedies used for inflammation of the eyes, I believe the best local application to be a strong solution of nitrate of silver, placed upon the ulcer with a camel-hair brush. When they are healing, these ulcers become slightly opaque, and their cicatrices resemble those of ordinary ulcers.

The acute ulcers of articular cartilage are, like those of the cornea and other parts, uneven and roughened by the fragments of tissue which are being loosened from it and dislodged piecemeal. There is, however, a chronic ulcer of cartilage corresponding with the state of the cornea just described, in which the particles of the tissue seem to be separated in very minute fragments, as well as slowly, so that no distinct layer of them in a disintegrated state can be seen upon the ulcer. At any rate, the surface of the ulcer is quite clear, and it looks as if a portion had been sliced off from the cartilage, or scooped out from it with a sharp instrument. These ulcers are found combined with the acute ulcers in amputated joints, and they sometimes exist alone. I have seen similar ulcers upon the opaque indurated wall of an ovarian cyst, and upon a vagina which had been long subject to inflammation.

The healing of ulcers in the cornea, and in cartilage, probably takes place without suppuration, and without the formation of that structure intermediate between lymph and cicatrix, which we call granulation. It appears that the lymph shed upon the surface of the ulcer is at once converted into a toughish opaque fibrous substance, which fills up the little chinks in the chasm, and forms the cicatrix.

All ulcers are, probably, more or less directly dependent on inflammation, and most of them are, in the rate and extent of their progress, proportionate to the severity of the inflammation which induces them. Some are more rapid in their increase than the attendant inflammation is sufficient to explain, and the disproportion between the cause and effect seems to depend upon some peculiarity in the ulcerating process. In others, again, the disproportionate rapidity of the ulceration depends upon a want of proper resisting power in the tissues to withstand the destructive tendencies of the inflammatory process. These three conditions enable us to group the various ulcers which fall under our notice into three great classes. The first we will call the inflammatory; the second, the phagedenic; and the third, the atonic.

Of the inflammatory ulcers some are acute and some are chronic, but all are dependent on the surrounding inflammation for the rate of their progress, and are proportionate to it; and, in the treatment of them, we

rely almost entirely upon measures calculated to reduce the inflammation. Of all the different varieties of ulcer the acute inflammatory is the simplest and most manageable; it commences at the point where the inflammation is most acute with a small blister or pustule, which, bursting, leaves an abrasion of surface or an ulcer. The ulcer continues to increase so long as the surrounding inflammation remains unabated. As soon as the inflammation subsides under the antiphlogistic regimen, with rest, and the application of fomentation or poultice to the part, the ulcer begins to clear, assumes a healthy aspect, and generally heals up quickly. In some particular cases, leeches, or even general bleeding, may be required. I would advise you not to apply the leeches upon the inflamed integuments surrounding the ulcer; they will do more good if placed at a greater distance, and the leech bites are less likely to be troublesome. These acute inflammatory ulcers are often the results of injury,—a contusion, abrasion, or laceration of the integuments, which is followed by inflammation and ulceration. They are frequently observed in healthy persons, and, for the most part, yield readily to appropriate treatment.

In chronic inflammatory ulcers, the ulceration and the attendant inflammation are slow in their progress, often remaining stationary, or advancing but little for months, so that the surrounding integuments and other structures become altered in colour, indurated, and adherent together, from the deposit of lymph into and between them. These changes may extend deeply into the limb, causing thickening of the bones, and adhesions of tendons to their sheaths. Chronic ulcers are sometimes the remnants of acute ulcers, or the consequence of neglected wounds, but very frequently they owe their existence to some disordered state of the constitution. They are most commonly met with in persons who have attained or passed the middle period of life, are far more frequent in the lower extremities than in other parts of the body, and they are often associated with a varicose state of the cutaneous or subcutaneous veins.

The liability of the lower extremities to ulcers and other chronic inflammatory affections, is, no doubt, dependent upon their comparatively imperfect organization and the proportionate languor of their circulation. It may be also, in some measure, related to the fact that they are in their development behind most of the other parts of the body, for, as a general rule, parts which are last developed are the first to fail. The decay of the body is foreshadowed by that of the teeth, the wisdom teeth being first, and the incisors last to go. The senile death of the lower extremities sometimes precedes that of the rest of the body by a considerable period, and we cannot wonder that parts which are thus at a comparative disadvantage, both as regards development and nutrition, should often suffer from the destructive effects of inflammation.

The relative facility with which the supply of blood is conveyed to the different parts of the body may be demonstrated by injecting the arteries of the dead subject from the thoracic aorta, as it is usually done preparatory to dissection. The injection first finds its way into the arteries of the trunk, head, and face, then

into the upper extremities; and it reaches the legs and feet last of all, and with the greatest difficulty. This comparative disadvantage with regard to the distribution of the blood, associated as it is with deficiency of nutritive force, must increase the liability of the lower extremities to inflammatory attacks and must render them inferior to other parts in the power of resisting the destructive effects of inflammation, as well as inferior in the ability to repair the breaches caused by inflammation and other causes.

Again, the ulcers on the legs are often associated with varix of the saphena and other veins—a condition which still further impedes the circulation through the integuments, at the same time that the distended and tortuous veins are a perpetual source of irritation, frequently exciting inflammation, and therefore directly predisposing to ulceration. These various causes,—viz., the late development and imperfect nutritive energies, the natural languor of the circulation, increased as it often is by a varicose state of the veins together with much exposure to injury, combine to render the lower extremities, particularly the skin of the legs, so much more susceptible of chronic ulceration than other parts, that, in its simple form, it is an affection almost peculiar to them. We very seldom see a chronic ulcer in the head, trunk, or upper extremities except it be of specific nature, or in a scrofulous patient.

These chronic ulcers of the legs form a considerable proportion of the cases admitted into our hospitals, and they present a great variety of appearances. The most characteristic features are an oval or circular shape, an excavated, dirty, grey surface, mottled with small reddish spots, and surrounded by raised indurated integuments which, at the margin of the ulcer, are often covered by a thick, soft, white layer of cuticle. These ulcers commonly furnish a large quantity of thin dirty fluid. The leg is generally oedematous, especially if the patient continue to walk about upon it, and the veins are frequently varicose, either in their minute cutaneous ramifications, or in the larger trunks which pass beneath the skin, and not infrequently in both situations. Sometimes the ulcers are covered with large, pale, flabby granulations, which reach or exceed the level of the surrounding skin; the discharge is, in such cases, also copious, and the integuments for some distance round the ulcer are bluish or livid. At other times the ulcer is more painful, its surface red, its circumference angry and irritable, and the discharge is red. It is useless to attempt a description of the various appearances these ulcers present, for scarcely any two are alike. They are confessedly tedious troublesome cases to manage, and you will see various means of treatment employed. We generally place the patient in the recumbent posture, and apply poultices to the part till the surrounding inflammation is abated, and the surface of the ulcer cleaned from the foul discharge and the dirty substance which usually covers it; afterwards water-dressing is employed, or stimulating lotions, if the ulcer be languid in appearance and progress. Pressure by means of a bandage, or with circular strips of adhesive plaster carefully applied, is sometimes very serviceable. The good effects of strap-

ping are especially observed when the ulcer is callous, as it is called,—that is to say when its edge is raised, indurated, and white. You will be surprised to see how quickly ulcers of long standing will sometimes heal up under moderate pressure, with well applied strips of plaster. The great success attending the employment of this plan of treatment in some cases has led to its indiscriminate adoption, and has necessarily caused it to fall into some disrepute. It does not answer when the ulcer is angry, or the surrounding integuments red and irritable. The emplastrum plumbi spread on calico may be sometimes advantageously substituted, when the skin is likely to be fretted by the resin of the emplastrum adhesivum. It is not always necessary to keep the patient in bed while under this treatment; indeed, the exercise of the limb and of the body may occasionally assist in the cure.

When the ulcer is angry, irritable, and painful, and the patient restless and unable to sleep, great benefit is often derived from the employment of opium, in doses of half a grain or a grain, given two or three times a day. If the surrounding integuments be adherent to the subjacent parts, and shiny from former inflammation or ulceration, the cure has to be effected by cicatrization alone, unaided by contraction,—is consequently very tedious, and the case is most unsatisfactory, because the ulcer is sure to break out again as soon as the patient walks upon the limb.

An ulcer which has shown little disposition to heal, will sometimes close up rapidly after an attack of erysipelas, or any other illness; and the sudden healing of an ulcer which has lasted for a long time is very likely to be followed by some other disease,—a cutaneous eruption, indigestion, or even apoplexy. When you inquire into the history of a chronic ulcer, you will often find that it was preceded by some disorder of the health, which subsided upon its appearance; and, if the ulcer has been at any time healed, the patient will often state that during that period he felt unwell, suffered under easy sinking sensations at the pit of the stomach, diarrhoea, loaded condition of the urine, loss of appetite, indigestion, giddiness, or some other disorder of the system. Sometimes the ulcers occur in women at the time of the cessation of the catamenia, and are a substitute for the flushings and other ailments often attendant upon that change. It is the more important to inquire into the particulars of all these cases, because during the time that the patient is under treatment, on account of the ulcer, these various constitutional symptoms are not generally present, and we are, therefore, likely to fall into the error of regarding the ulcer as the only ailment, and to imagine that in healing it we are curing our patient.

Attention to the constitutional symptoms forms, therefore, an important item in the treatment of chronic ulcers, and you should consider, not merely those symptoms which exist at the time, but those also which preceded the ulcer, and those which, from your observation of the patient's constitution, are likely to follow if it be closed. The particular course to be adopted in reference to these symptoms must vary with the circumstances. When the ulcer is of long standing, it is not

wise to close it up completely, for no course of general treatment can ensure your patient against the occurrence of some other disease. Even the imitation of the plan which nature has adopted,—viz., the furnishing a vent by means of a seton or issue answers but imperfectly, and the patient is often content to bear an ailment which has become habitual, rather than encounter a new disease under the name of a remedy.

A very troublesome ulcer with indolent, granular, or warty surface sometimes forms under the cuticle of the fingers, or palm of the hand, where it has been thickened by pressure, or under a corn upon the sole of the foot or at the heel. The only plan of treating these cases which I have found effectual has been, after paring away the thickened cuticle, to apply nitric acid to the surface of the ulcer, so as to destroy the warty structure, and present a fresh surface, upon which the healing processes may do their work.

ON THE TREATMENT OF HERNIA WITH OPIUM.

By BUTLER LANE, M.D., M.R.C.S.E., Ewell.

In the *Provincial Journal* of April 21st, 1847, I published a paper advocating the treatment of hernia with opium, and I now again take an opportunity of adverting to the subject, with the view to urge my professional brethren to give a more general trial to this simple and efficacious mode of treatment. The striking case related by Mr. Mayo, of Winchester, in the *Journal* of June 16th, 1847, and the editorial reference to other cases successfully treated by the opiate plan, I hoped would have elicited some further communications. Such, however, has not been the case, but if those who have given the opiate treatment a trial, whether successfully or unsuccessfully, would inform me on the subject, I should be happy to embody the results of their experience for the general advantage.

Since my former communication the two following cases have occurred to me:—The first was one of inguinal rupture in a young man. On a former occasion, some months previously, I had reduced it with some little trouble, but now, from over exertion in bell ringing, it was forced down into the scrotum, and presented the volume of a small orange, firm and elastic to the touch, and affording the usual impulse on coughing. The taxis failed in its reduction, as also did the application of cold. There was then no sickness, and the pulse was quiet. An aperient was given, and the bowels were relieved, but, as I doubted whether action had taken place through the entire course of the alvine canal, it was repeated. The second dose operated three times, and caused much burning stinging pain in and at the neck of the tumour. It was thus evident that the hernia was incarcerated, but not yet strangulated. The next day the tumour was found the same. An attempt at reduction was again made by myself, and subsequently by my friend Mr. Allan, of Epsom, without success. Towards evening some

symptoms of constitutional irritation became manifest, —viz., accelerated pulse, dark-coloured vomiting, with local and general abdominal pain and tenderness. No further action of the bowels had taken place. Opium was now resorted to in grain doses every hour, and by the time the man had taken six doses he was powerfully narcotized. Still the hernia was not returnable, though all pain had disappeared. A castor-oil enema was thrown up the rectum with an œsophagus tube, but after some time it returned untinged with fecal matter. The stomach being no longer irritable, it was thought desirable to administer a mild aperient draught, and leave the patient for the night. On an early visit the following morning, all trace of the tumour had disappeared, though how or when, the patient was quite unconscious. The bowels were relieved soon after, but so strong was the opiate influence, that I believe the man slept almost incessantly for the next twenty-four hours.

The second case was that of a shepherd, who had trained himself in managing some sheep. On the left side I found an old irreducible and painless inguinal hernia; on the right side was a smaller femoral one, about the bulk of a small egg, which, according to his own account, had not been reduced for a month or two, but was now increased to double its original size by the injury which he had received two hours previously to my seeing him. He had made many ineffectual attempts to reduce the rupture, and I also failed with the taxis. The tumour was tender, painful, and very tense; the entire abdominal surface was also painful and acutely sensitive to the slightest pressure. There was nausea and retching. Being called away suddenly, I placed two grains of powdered opium, with the same of calomel, on the man's tongue, and left him on his back. On my return, in three-quarters of an hour, I found that the hernia had wholly disappeared, and that my patient was quite relieved. He told me that after I had left him about fifteen minutes, he began to feel easier, and experienced a gurgling and rumbling in the bowels. He then made moderate pressure on the tumour, and it quickly disappeared.

I have also been favoured with the narration of a case which occurred in the practice of Dr. Thorn, of the Harrow Road, Paddington, of which that gentleman ascribes the successful issue to the adoption of my recommendation of the *opiate treatment*. It was a case of inguinal hernia, occurring in an old lady, aged 68, who obstinately refused the application of the taxis and other appropriate means. There was obstinate constipation, which had existed ten days; the vomiting was also stercoraceous; there was hiccough and intermitting pulse. Purgatives and other medicines were useless, and she seemed fast sinking into a state of collapse. Tincture of opium was then resorted to; and half an ounce was given in small and gradually increased doses, at intervals of two hours. With this she rallied, becoming more comfortable and easy, and an enema brought away a quantity of feculent matter, with blood and membranous substance. Pain and sickness still continued, probably from the supervention of inflammatory

action; but, with the sanction of Professor Fergusson, the opiate treatment was persisted in, combining calomel with Pulvis. Opii. Sixteen grain doses of the opium were given, with double the quantity of calomel, at intervals of two hours. Subsequently half an ounce more laudanum was administered, in moderate doses, and a further quantity of opium, with calomel, was rendered necessary, by a subsequent attack of enteritis. The patient is now in health, and, as Dr. Thorn emphatically remarks, remains "*a living testimony of the efficacy of opium.*" The case is certainly a remarkable instance of bold and successful practice.

The advantage to be derived from the administration of opium in hernial cases, may, I believe, be regarded as two-fold. Firstly, in subduing the general and local irritation, it will materially augment the chance of reduction; secondly, should it finally be necessary to resort to the operation, I am confident that the treatment in question will place the patient in the condition most favourable for the performance thereof, more or less anticipating and preventing the constitutional disturbance which would be liable to occur. The partially anæsthetic condition, as we may term it, which is instituted by the administration of opium, is of a decidedly genial character, tending rather to promote than depress the vital powers, a fact well illustrated by Dr. Thorn's case, and which indeed must be familiar to all practical men. In the first of the cases which I narrated in my former paper, the conversion of a state of almost mortal collapse into one of happy inebriety was most striking, and in a case which I believe will shortly be brought under the notice of the readers of this Journal, wherein the operation was necessitated after the opiate treatment had been resorted to, I have been informed that the insusceptibility of the patient to constitutional irritation was remarkable, even though subsequent mortification of the gut took place, occasioning the temporary formation of an artificial anus. It may be made a question, whether there is no risk of masking the acute symptoms of strangulated hernia, and thereby causing the operation to be delayed, to the material diminution of its probable success. Now, to those cases where the operation is obstinately refused, this argument will not apply, inasmuch as the opiate treatment may be regarded as a compulsory alternative; and I feel convinced that as a general rule, even in other cases, where an operation would readily be submitted to, no advantage would be lost by giving the opiate treatment a due trial. A greater delay than it would require, is often at present accorded, without even a rational prospect of relief, and without the constitutional benefit being realized, which I anticipate from the the opiate treatment. Supposing the necessity of an operation is somewhat urgent in the judgment of the surgeon, I cannot believe that a dread of masking symptoms need deter him from administering opium; no man would be justified in knifing a case without the previous trial of some milder means; therefore let him fix the latest minute to which he deems the operation may be deferred, and if, when the hour of grace has expired, the administration of opium,

simply or in combination with other remedial measures, shall have afforded no *essential relief*, then let him be "*bloody, bold, and resolute.*" I should not deem either abatement of pain or arrest of vomiting, individually, to constitute *essential relief* in themselves, but if the subdual of those two distressing symptoms were combined with considerable constitutional relief, (I do not mean narcotic stupor,) then, although defecation should have taken place, some further delay would surely be justifiable.

I will not further trespass on the valuable columns of our Journal, but trust that what I have written may induce some of those to whom the field of surgical experience is more widely open than to myself, to give a trial to the opiate treatment, fairly examine its merits, and faithfully report the results of extended experience.

Ewell, Surrey, May 1, 1849.

ON THE

USE OF THE EXTRACTUM COTYLEDONIS UMBILICI IN EPILEPSY.

By JOSEPH BULLAR, M.D., Southampton.

The large number of epileptics who are not treated at all, is one of the strongest proofs of the insufficiency of our present means, and the best apology for bringing forward a new remedy, and as this remedy is an indigenous plant which is now in full leaf, and grows plentifully in many parts of England, many of the members of our Association may be induced to try it. I will, therefore, shortly state my experience.

Several years ago the expressed juice of the cotyledon umbilicus or napplewort was recommended to a lady who had compound epilepsy, which had not yielded to medical treatment, and under its use the disease was entirely removed and has not returned. The patient was under the care of my friend Mr. Salter, of Poole, who watched the case with much interest, and mentioned the fact to me. Subsequently, my brother, Dr. W. Bullar, recommended the juice for a child in this neighbourhood, where the plant grew, and the epilepsy was cured. Rather more than a year ago I requested Mr. Randall, chemist, of Southampton, to prepare an extract of the expressed juice, in order to give the remedy a trial, and from the experience I have since had, I have no doubt in my own mind of the anti-epileptic power of the medicine, although sufficient time has not yet passed to bring forward cases as perfect cures. Mr. Salter, having, however, published the case just mentioned, in the *Medical Gazette*, and alluded to the use which I have made of the extract, which has interested many, I am rather anxious to state what results may be fairly expected, in order to prevent disappointment to those who may use it.

From the experience I have had in a considerable number of cases, (several of which were of a very hope-

less kind,) long perseverance is necessary, and if the number and violence of the fits are lessened, there are good grounds for hope and further perseverance. In all the cases there has been a marked diminution in the violence and frequency of the attacks; and as, in two cases, (one of which I heard to-day,) it has first increased the violence of the fit, and as in others there have been transient symptoms of increased nervousness and headache, requiring a short suspension, I am in hopes that it may prove a true anti-epileptic. It is certainly in many cases nervo-tonic, as the improved nervous tone is shown by quieter sleep, fewer dreams, better spirits, more ability to take exercise, and a consciousness of general improvement. It has no other action on the body that I am aware of. It certainly produces no action on the bowels, for when there has been costiveness (which is so commonly the case in epileptics) the usual medicines to keep up a natural action have been required. I have used it with the precautions quinine requires in ague, attending to the general health, and endeavouring to remove and rectify faulty secretions, or any obvious local disorder. Some of the patients to whom I have given it have been in fair bodily health; in others the nervous system has been weak and excitable; in others weak and exhausted. In children it is advisable to begin with a few brisk purgatives, in case the epilepsy may depend on worms; and in young men the state of the urethra should be examined, as that state of debility kept up by seminal discharges, consequent on an irritable urethra, which so disposes the system to epilepsy, counteracts the beneficial influence of the medicine. If there is habitual costiveness, a simple dinner pill (as the compound rhubarb,) is necessary. When, with an excitable nervous system, there is a foul tongue, yellowish eye, turbid acid urine, and offensive motions, the state of the blood on which this depends must be corrected by a course of aperients, which excite the gastro-intestinal mucous membrane, liver, and kidneys, to throw off the impurities, without weakening the general powers, (aided by diet and hygienic means,) for unless the fluids are thus filtered and purified, no specific remedy can with any reason be expected to have a fair chance. I will briefly relate two cases which have impressed me strongly with the powers of the medicine, and the importance of steady perseverance.

One of these patients had been epileptic for some years; she was of an excitable nervous system, and had suffered much anxiety. During the year which preceded the use of the cotyledon, she had attacks of epilepsy every three weeks, the attacks consisting of eight or nine fits, lasting from twelve to twenty-four hours. She has, with few intervals, taken the cotyledon since April 1848, and she has had but one fit during the last seven months, and that a slight one. Her health was improved.

The second was a younger woman, about 22, who had been epileptic since she was six years old. She was muscularly strong, and her general health good, except costiveness, and slight leucorrhœa. The fits occurred once or twice a week, occasionally (but rarely)

there was an interval of three weeks. No remedies had been of any use. She began to take the extract in April, and continued it until October, with a few intermissions. The fits had become very few, and more like short fainting fits, in which she did not lose her consciousness. In November she went to France, and I learned a fortnight ago that she had had but two of these slight fainting fits since, and six months have elapsed.

Now, neither of these cases can be strictly said to be cured, the fits may return, but yet they are sufficient evidence to justify perseverance in other cases; for epilepsy does not wear itself out, but wears out the brain and the mind.

Through the kindness of the attendant surgeon I had an opportunity last year of trying the extract of cotyledon in five patients who were incarcerated for life in the workhouse, on account of epilepsy; they had been epileptic for 5, 8, 12, 30, and 58 years, and in all, the mind was weakened. I did not persevere more than three months, as the attacks, though fewer, still returned. Subsequent experience having shewn me that much greater perseverance was necessary, I examined the notes of these cases, and found on comparing the difference between the number of fits which the patients had before the use of the extract, and those which occurred during its employment, so striking a diminution as to supply confirmative evidence of its power.

The juice is prepared by bruising the leaves and leaf-stalks in a mortar, and expressing the juice from the bruised mass through a cloth. One teaspoonful twice a day of the juice. I have prescribed five grains of the extract, (which is made by evaporating this juice,) twice a day, and occasionally three times. It may happen that the disease may be much shortened by increasing the dose. This is matter for further trial. With a new remedy I have been cautious.

The cotyledon umbilicus grows very abundantly in Great Britain and Ireland; it is now in full leaf. It grows in Hampshire and Dorsetshire, on road-side banks and on stone walls. It has a thick, fleshy, light-green leaf, almost circular, with its fleshy foot-stalk inserted in the centre of the leaf, so as to give it a shallow cup-like or umbilicated depression. I have heard of it as matlock, in North and South Wales, and at Ilfracombe. Mr. Jones was kind enough to send me a considerable quantity from Jersey. The friends of a lady, (who is now taking it in Dublin,) have found it abundantly near that city, where the poor use it as poultices. Professor Balfour, of Edinburgh, tells me that he has gathered it in many places on the west coast of Scotland, and near Galway, in Ireland, as well as in England.

I should be very much obliged if any member of our Association, who may try this remedy, would favour me at some future time by sending the particulars of his cases, as I hope, when time has added confirmation to my experience, to communicate more in detail to the Society the results.

I cannot finish this communication without repeating that disappointment will surely follow, if the patient

and the practitioner are not willing to persevere, and unless, besides the assumed specific, each case is not treated for its individual peculiarities. But as epilepsy is an intermittent, with intervals often of six months, a short cure is not to be expected, and no treatment is rational in any case unless strictly individualized.

REMARKS, HISTORICAL AND PRACTICAL, ON DISEASES OF INFANTS.*

By E. COPEMAN, M.D., NORWICH,
Consulting Accoucheur to the Norwich Lying-in Charity.

In 1767 an account of the diseases most incident to children was published by Dr. George Armstrong. It does not appear that the diseases of children were much studied or understood in this country before the publication of Dr. Armstrong's work, for he speaks of hydrocephalus almost as a novelty, and the possibility of its being cured but just ascertained. In his remarks on the diseases of children in general, he ably refutes the opinion, at that time very prevalent, and even now by no means universally discarded, that because infants have not the means of expressing their feelings, or describing their complaints by words, there is nothing to be done for them when ill, owing to the difficulty the physician has to encounter in endeavouring to ascertain the nature of their diseases. It would be out of date now to enlarge upon this subject, the prejudice against the medical treatment of children's diseases is confined almost to old women, and but few of the present race of educated medical practitioners will not acknowledge that, to say nothing of the interest necessarily connected with the power to contribute to the relief of the most helpless and interesting part of creation, there is but little more difficulty in distinguishing and treating the diseases of infancy than those of adult age; indeed, in many respects, there is less. In infancy there is no guile, there are no evil habits to counteract; in infancy disease runs a more *natural* course, is less biased by the counteracting powers of moral and physical intemperance; in infancy there is more certainty in the action of medicines, less disappointment in their effects, so that if the use of them be properly understood, their beneficial influence may be more safely relied upon. It is true that ignorance renders the treatment of infantile diseases not only difficult but extremely hazardous, but knowledge is power, to the effectual relief of many little sufferers.

Dr. Armstrong considers *inward fits* the most common complaint incident to infants. "The child appears as if asleep, only the eyelids are not quite closed; and if you observe them narrowly, you shall see the eyes frequently twinkle, with the white of them turned up. There is a kind of tremulous motion in the muscles of the face and lips, which produces something like a smile, or sometimes almost the appearance of a laugh. As the disorder increases, the

* Continued from page 72.

infant's breath seems now and then to stop for a little, the nose becomes pinched, there is a pale circle about the eyes and mouth, which sometimes changes to livid, and comes and goes by turns; the child starts, especially if you go to stir it, though ever so gently, or if you make any noise near it. Thus disturbed, it sighs, or breaks wind, which gives relief for a little, but presently it relapses into dozing. Sometimes it struggles hard before it can break wind, and seems as if falling into convulsions; but a violent burst of wind from the stomach, or vomiting, or a loud fit of crying, sets all to rights again." He speaks of the dangerous consequences of a frequent repetition of these fits, and for the prevention and cure of the complaint, particularly insists upon the child never being laid down to sleep after taking food, till it breaks wind upwards or downwards two or three times; a gentle puke is to be given if necessary, the child preserved from cold, and kept as dry as possible, the limbs and belly being rubbed frequently, and for a good while together, before the fire. He considers convulsions, in most instances, a symptom, and not a disease, often closing the scene in adults as well as in infants. Of hydrocephalus he appears to have possessed but very imperfect notions, and believed it quite incurable until he became acquainted with a case published by Dr. Dobson, in which recovery was effected by means of calomel carried to ptyalism. This case, another communicated by Hunter, and a third, which occurred in his own practice, he has inserted, in order to exemplify the mode of treatment by calomel, and to represent the possibility of cure.

In 1768 appeared "Observations on the Dropsy of the Brain," by Robert Whytt, M.D., Professor of Medicine in the University of Edinburgh. This was perhaps the first essay published in this country professedly on *hydrocephalus*, and it makes an important era in the history of this serious disease, being still considered one of the best descriptions of the affection. Whytt describes hydrocephalus as "either external or internal; the former has its seat in the cellular substance, between the skin and the pericranium, or between this membrane and the skull; in the latter the water is sometimes collected between the *cranium* and *dura mater*, or between this last and the *pia mater*, but most commonly in the ventricles of the brain, immediately below the corpus callosum; and this is not only the most frequent and fatal species of hydrocephalus, but also that with which medical writers seem to have been least acquainted." The youngest infants are not so subject to this kind (internal) as children of two years and upwards. "Of about twenty patients whom I have seen die of the distemper, one only was under half-a-year old, the rest between two and sixteen." He divides the disease into three stages: "the *first* comes on four, five, or six weeks, and sometimes even longer, before death,—is always attended with some degree of fever, sometimes much, sometimes little, and is more particularly characterized by vomiting once or twice a day, or once in two or three days, headache and aversion to light, the bowels being commonly costive, though sometimes

they have returns of a looseness. The *second* stage is dated from the time the pulse, from being quick but regular, becomes slow and irregular; this sometimes happens about three weeks, often a fortnight, or less, before the death of the patient. The diminished frequency and irregularity of the pulse, *the heat of the skin continuing much the same*, are the chief diagnostic marks of the second stage. When the pulse rises again to a feverish quickness, and becomes regular, the *third* stage may be said to begin; and this change in the pulse is observed five, six, or seven days before death. In this stage the patient who, before, was little disposed to sleep, becomes drowsy and comatose, one eyelid, and afterwards the other, become paralytic, the pupils are inactive; the patients are sometimes observed to be constantly raising one of their hands to their head, and are generally troubled with convulsions of the muscles of the arms, legs, or face, as well as with a *subsultus tendinum*. Those who have been costive before often become loose in the third stage, and complain of gripes."

In ten cases examined by Whytt after death he found a clear thin fluid, generally from two to five ounces, in the ventricles of the brain, but never met with water between the *dura mater* and the brain, between the hemispheres, or immediately above the corpus callosum. The fluid did not coagulate by heat.

In the treatment of hydrocephalus Dr. Whytt employed repeated purgative doses of rhubarb and jalap, with calomel, and blisters, but he frankly confesses that he had never had the luck to cure a patient who had those symptoms which with certainty denote this disease.

In the fourth volume of "Medical Observations and Enquiries, by a Society of Physicians in London," there are three papers on hydrocephalus, one by Dr. Fothergill, read August 8, 1768, and two by Dr. William Watson, the respective dates being August, 1768, and April, 1770. From the observations of Dr. Fothergill, it would seem that he had but an obscure notion of the disease, and could with difficulty distinguish it from symptoms supposed to proceed from worms; and as to treatment, he observes—"I must own that it is not in my power to suggest any probable means of curing the disease; it has baffled all my attempts, both when confided in alone, and in consultation with the ablest of the faculty." He describes the disease as seldom occurring in subjects younger than three years, most frequently from five to ten; two or three cases happened from ten to thirteen, and two between seventeen and nineteen years of age. The last four were girls, the former mostly boys, and none of them were peculiarly unhealthy before they were attacked with the disease. Most of them had gone through the small-pox, some the measles likewise; but without any reason to suspect that these had left any foundation for this terrible complaint. Dr. Fothergill differs from Dr. Whytt, with respect to the insidious nature of an attack of hydrocephalus, and says, on the contrary, he has seen children, who, from all appearance, were well, healthy, and active, seized with this distemper, and carried off in about fourteen days.

In Dr. Watson's paper, attention is directed in the first instance to three cases of hydrocephalus; they were all girls; the first six, the second nine, the third fourteen years of age; and they all terminated fatally. "Not only the three cases above mentioned, but several others that have fallen under my notice, have all been fatal; nor has better success attended other physicians both here and elsewhere." The principal feature in Dr. Watson's second paper, which he terms an appendix to the first, is a case which terminated successfully; this was the only instance he had seen of recovery from dropsy of the brain, when, from the attendant symptoms, little doubt remained of the disease being completely formed. It is certainly a remarkable instance of recovery from severe cerebral disease, and exemplifies the remedial power which nature occasionally exercises, even in desperate cases, when not interrupted, but only gently assisted by the interference of art. It teaches us the double lesson,—never to despair, and not to do mischief by overmuch activity.

In the fifth volume of "Medical Commentaries," published 1777, Dr. Percival has given a case of hydrocephalus, in which he thought great good had resulted from the free use of mercurial frictions, by causing absorption of the fluid in the brain, which had produced a manifest tremor at the bregma. His patient, however, died; and in a letter published in the same volume by Dr. Simmons, the latter physician expresses great doubt as to the fluid having been removed by the action of the mercury, and attributes it rather to the several blisters that were applied to the head, and to the application of linen dipped in brandy to the seat of the swelling. It is very probable that both were right, and both wrong, and that the absorption of fluid was the result, not of the local treatment only, but of the conjoint influence of local and constitutional remedies.

In 1779, Dr. Quin published a thesis on internal hydrocephalus, in which he offers a different view of the nature of the disease to that which had before prevailed. The new doctrine propounded by Dr. Quin was to the effect, that the causes of acute hydrocephalus are of a very different nature to those of simple dropsies, (the opinion hitherto entertained,) and are much more closely allied to the causes of acute diseases; and that, in fact, this disease always owes its origin to a morbid accumulation of blood in the vessels of the brain, sometimes proceeding to a degree of inflammation, and generally, but not always, producing an extravasation before death. The opinion which this thesis appears to have originated, that acute hydrocephalus depended upon congestion and inflammation, has had numerous supporters from that time to the present, and has led, as might have been supposed, to the adoption of various degrees of antiphlogistic treatment for its cure.

A few years afterwards, Dr. Michael Underwood published his famous "Treatise on Diseases of Children." The first edition appeared, I believe, in 1784, the fifth in 1805, and the tenth in 1846, edited by Dr. Henry Davies. Other editions have appeared under the superinten-

dence of Drs. Marshall Hall and Merriman; and that recently published by Dr. H. Davies bring up the subjects contained in the treatise to a level with the improvements of the present day. No greater proof of merit in the original work can possibly be accorded; for, from its first appearance to the present time, it has been considered, with the editorial additions and improvements it has at various periods received, a standard authority in this country on the diseases of infants and children. Dr. Underwood was Physician to the British Lying-in Hospital, and from his eminent position in London, enjoyed also ample opportunities of witnessing the diseases of children amongst the highest classes of society. His opportunities for observation were turned to good account by the industrious workings of a powerful mind, and a benevolent desire to promote diffusion of knowledge upon a subject of great interest, but which before his time had not been either widely or successfully investigated. He says, in the preface of his fifth edition, "Prompted by a laudable ambition of being useful in his generation and leaving behind him something beneficial to posterity in the only way he could attempt it, he is persuaded the benefit will not terminate here; but that others will be excited to perfect this long neglected, but most important branch of the profession." How well the anticipations of the author were founded, and how completely they have been fulfilled, are most amply attested both by the future career of his own book, and by the great industry and talent since brought to bear upon the same department of medicine.

Inward fits, a disease much insisted upon by Armstrong, is scarcely noticed by Underwood; indeed, he says he knows no complaint that deserves the name, and considers the symptoms to be merely the effect of a little wind upon the stomach; or, when accompanied with spasm, to be chronic croup, which he always succeeded in removing by the administration of different antispasmodics. Whether or not it be right to acknowledge *inward fits* as a distinct disease, the term does refer to symptoms which it is exceedingly important to observe. It is of great importance for them to be recognized by the mother or nurse; and as the appellation has been familiar to nurses and old women for ages,—and they are extremely tenacious of what is handed down to them by their predecessors,—it is better to give the term a definite meaning, than to abolish it altogether. I was once much struck with an observation of a nursemaid, of no very great experience, about an infant a few days old, who, to all appearance, was perfectly well and healthy. She remarked to the monthly nurse that she had *once or twice* noticed an appearance about the eyes which she thought would turn out to be fits or water in the head. I watched the child very carefully in consequence, but could never, during my visits, nor could the nurse, detect the slightest appearance of disordered health. After awhile, however, the baby suffered from wind and acidity, which were soon removed by suitable remedies; afterwards a mild thrush appeared, but again the child regained its health. It was vaccinated at two months, and passed

well through the disease. Soon after this I lost sight of the infant; it was removed to the sea-side; whilst there was attacked with diarrhoea, a disease then very prevalent, and died, I was told, with symptoms of water in the head. How valuable is the knowledge of any tendency to head affection, in the treatment of diarrhoea, or any other disease in infancy, and consequently, how important for nurses to understand, and be able to communicate to the physician, any symptom, however slight and temporary, that may be calculated to arouse his vigilance or influence his treatment. The above narrative shews that those who are in constant charge of an infant may occasionally notice a suspicious circumstance, which does not present itself to the view of the medical attendant, and from this I deduce an argument in favour of encouraging, amongst nurses and mothers, a knowledge of the symptoms of *inward fits*, instead of banishing it from the catalogue of diseases; not for the sake of enabling them to treat therapeutically, but that they may be competent to give due warning of the necessity for proper medical advice.

At the close of the last century, an "Inquiry into the cause and cure of the Internal Dropsy of the Brain," by Dr. Rush, was published at Philadelphia, and forms one of the papers in the second volume of his "Medical Enquiries and Observations." Having been unsuccessful in all but two cases of internal dropsy of the brain, which came under his care, Dr. Rush was led to entertain doubts of the common theory of the disease, and to suspect that the effusion of water was only the effect of inflammatory disease in the brain. In accordance with this view of the nature of the disease, he resolved to alter his mode of treatment. The first remedy indicated was blood-letting, and he quotes seven cases, which all terminated successfully after free blood-letting, assisted by purgatives and topical applications. "When blood-letting," he remarks, "has failed of curing this disease, I am disposed to ascribe it to its being used less copiously than the disease required; and since I have adopted depleting remedies, I have declined giving mercury altogether, except when combined with some purging medicine," because of the uncertainty of its operation, its frequent inefficacy when it excites a salivation, and above all, its disposition to produce gangrene in the tender jaws of children.

(To be continued.)

COMA RESULTING FROM RETAINED BILIARY SECRETION.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

Dr. Ranking has published an interesting case in your Journal, (May 3rd, 1848,) showing how coma may be caused by retained biliary secretion. There can be no doubt that the brain may be affected in various and even opposite ways by the same cause. A

few years ago I met with a well-marked case of retention of vitiated bile, in which excessive watchfulness was the most prominent symptom.

On the 16th of January, 1841, I was sent for to see a farm-labourer living in a village about four miles distant from my residence. He was in bed, complaining of general uneasiness, with nausea, constipated bowels, and slight headache; his pulse was about 90, full and soft; there was some heat of the skin, but the forehead was not hotter than any other part of the surface; the tongue was covered with a dirty fur; the eyes had a watchful and rather vacant appearance, and his wife said he had had no sleep for some time; there was no delirium. I looked on the case as one of deranged stomach and bowels, and without paying any attention to this statement about sleeplessness, I gave him an emetic, to be followed by a smart dose of calomel and jalap, and a saline mixture.

I did not see the patient again until the 18th, when I found the symptoms much the same. The nausea had been relieved by the emetic, but the aperient had acted very imperfectly on the bowels. He had never slept. I sent him another powder of calomel and jalap, to be followed by a grain of calomel, and a dose of senna and salts every four hours.

On the 19th I found the bowels had not been acted on at all, so I gave the man an enema, which brought away some scybala, and directed him to persevere with the medicine I had given him the day before. As his wife protested he "had never slept a wink since he had been taken ill," I sent him a grain of muriate of morphia in a draught, to be taken at bed-time.

20th. No sleep. Other symptoms the same. Bowels very slightly moved. Continue aperient mixture and calomel pills. I felt unwilling to give a night-draught again.

23rd Finding that perseverance with alteratives and aperients had made no difference with respect to the *insomnia*, of which both the man and his wife complained bitterly, I sent him two grains of muriate of morphia in a mixture, directing him to take half that night and the remainder the next, and ordered him to continue taking his medicine as before.

On the 24th, I found that, notwithstanding the man had made a mistake, and taken the whole of his sedative mixture at once, he had still been unable to sleep. The bowels still continued very sluggish. I therefore added some Pil. Cambog. Comp. to the calomel pills, and increased the strength of the aperient mixture.

On the 25th, I found him voiding an immense quantity of feculent matter of the exact colour and consistency of tar. The nature of the case was now becoming evident; the uneasy sensations were already somewhat relieved, and as there could now be no doubt as to the propriety of the course I was pursuing, I made him persevere with his medicine.

26th. I found the man going on quite favourably; he had slept pretty well, and felt quite comfortable; the evacuations continued copious, and of the same character as the day before. As that was the case, I thought it expedient that he should not discontinue the

alterative and aperient pan until there was some improvement in their appearance, which did not take place until about the 9th, after which the man was speedily quite well. Notwithstanding the quantity of calomel taken, the gums were not at all affected.

I am, Sir,

Your most obedient servant,

R. U. WEST.

Hogsthorpe, Alford, Lincolnshire,

May 14, 1849.

Hospital Reports.

QUEEN'S HOSPITAL, BIRMINGHAM.

CLINICAL REPORTS OF SURGICAL CASES UNDER THE TREATMENT OF PROFESSOR SANDS COX, F.R.S., SENIOR SURGEON TO THE HOSPITAL.

Reported by Mr. PETER HINCKES BIRD, late Resident
Medical Officer.

CASE XX.

TRANSVERSE FRACTURE OF THE FEMUR.

William Harris, aged 28, carpenter, admitted into the Queen's Hospital October 27th, 1846, under the care of Professor Cox. He states that about an hour since a large quantity of timber fell upon his legs and thighs; he immediately lost the use of his right leg, and experienced severe pain in the thigh.

On admittance it was found that he had lost the use of the right limb; the thigh was "bowed," but there was no apparent shortening; the foot and knee were turned outwards. On fixing the upper part of the femur, and on moving the lower part by grasping the knee, distinct crepitus was perceived; the inner edge of the foot appeared to be turned much upwards, but this he says is the result of an old sprain. The patient was placed on a hard bed, and Liston's long splint applied.

28th. Feels comfortable; there is no swelling.

November 13th. Doing well; the bone is in good position; callus can be distinctly felt on the outer side of the seat of the fracture; there is no shortening of the limb.

December 1st. Is out of bed; the limb is perfectly straight, and the bone is firmly united; can walk pretty well.

8th. Discharged.

In transverse fracture of the femur, the displacement may be very slight, and often none at all, for the fractured surfaces of the bone being flat and regular, form, when in contact, a mutual resistance to each other; the lower end drawn upwards by the muscles, meets with resistance from the upper one, which being itself inclined downwards by the weight of the trunk, pushes the former before it, and thus both retain their position in relation to each other. It is not, however, uncommon to find displacement in some cases of fracture in the transverse direction, and to a considerable extent, so as to produce great shortening of the

limb. This occurs when the force applied has been very violent, and has acted upon the ends of the bone after it has caused their fracture, so as to push them from their apposition; or the displacement may be also caused by ill-directed exertions in carrying the patient, the limb not being supported on the same level.

The apposition of the ends of the bone in the transverse fracture may also be disturbed by the action of the flexor muscles of the hip, which may tilt the end of the upper portion of bone upwards, and then the other muscles may pull upon the lower portion, and draw it behind or to one side.

When the fracture occurs just below the trochanter minor, this action of the flexor muscles is one of the chief causes of the displacement, and the most troublesome one to guard against. It is probable, however, that in the majority of cases, the action of the muscles has but little to do with the primary displacement, but that the force that produces the fracture first of all pushes the ends of the bone from their contact, and that the muscles are only secondary in their action.

Although in the transverse fracture there may not be always displacement with regard to the length of the limb, there generally is with regard to the long axis, for the lower portion may be rotated outwards, while the upper portion remains stationary; this was well seen in the above case. When the patient is placed on his back in bed, this rotation of the lower portion outwards becomes very apparent, by the extreme eversion of the foot and knee; and in almost all fractures of the thigh, whether it be through the neck or shaft of the bone, this is found to be a very prominent symptom. The cause of this rotation outwards is not, perhaps, fully accounted for; it is said that the muscles attached to the bone have a great deal to do with it; they have, no doubt, the power of producing it, but Lonsdale* does not believe that they often act in this manner, and there is quite a sufficient reason to explain it without having recourse to the muscles. He refers to the shape of the limb. The inner and outer edge of the leg and thigh differ greatly as to the line they form, and in the degree in which they support the limb posteriorly, when it is lying horizontally; for the inner side of the calf of the leg is much more fleshy, and extends more beyond the edge of the bone than the outer side, the consequence of which is, that when any pressure is made upon its posterior surface, it pushes this mass of flesh still more in this direction, and so presents a decided obstacle to the rotation inwards; whereas the outside of the leg is smooth and round, and presents a firm surface, which favours rotation in this direction, and more particularly since there is so great an obstacle to its being rotated in the opposite one. Lonsdale conceiving that the simple weight of the limb is sufficient to roll it outwards, when the shape of its outer surface is considered, and when the shaft of the bone is broken, and so having deprived the lower portion of its natural support. The upper portion cannot be rotated outwards, owing to the great trochanter, which will check motion in this direction when the patient is lying on his back, besides which, there is no disposition for the upper portion to roll either in this direction or inwards, for there is not the weight of the leg and foot to drag upon it now that

* A Practical Treatise on Fractures, p. 100.

the bone is broken, which there is upon the lower portion. This rotation always aggravates the displaced state of the fracture, and should be attended to in the reduction.*

The treatment of transverse fractures of the femur is much more satisfactory than that of fractures in the oblique direction, for if they are properly attended to, shortening of the limb seldom results.

CASE XXI.

COMPOUND FRACTURE OF THE LOWER JAW.

Thomas Bradley, aged 18, labourer, was admitted into the Queen's Hospital, October 4th, 1846, under the care of Professor Cox. He states that about two hours ago he was struck by a man's fist on the right side of the face, and afterwards on the left; on the receipt of the last blow he felt his jaw crack, "as if all his teeth were in his mouth." He walked more than a mile to the Hospital.

On admission it was found that the lower jaw was fractured nearly perpendicularly on the left side, the situation of the fracture being between the bicuspid teeth, the first of which was knocked out at the time. The gum was lacerated, and a probe could be easily passed down to the bone; the portions of bone were slightly displaced, the anterior or larger portion falling downwards and forwards, and the posterior being drawn upwards and inwards. The fracture was easily reduced. A piece of pasteboard was moulded to the shape of the lower jaw, and padded with cotton-wool, and retained by a four-tailed bandage. Ordered to keep quiet, and not to talk. Spoon diet.

5th. Slept well last night; some swelling and pain of the face; saliva dribbles away freely.

10th. Doing well; the bones are in good position, and the teeth are on a line. Made, at his own request, out-patient.

26th. Presented himself at the Hospital this morning; the fractured portions have firmly united; there is no deformity of the face.

The shape of the inferior maxillary bone and its prominent situation, render it very liable to fracture, when struck by a hard blow, or by any hard substance, especially on the part between the symphysis and the condyle. Fracture also generally takes place from a blow striking either the ramus or the base of the bone. The force required to fracture the bone in any part must be very great, for the manner in which it articulates with the skull, and its junction at the symphysis, give it great power of resistance. The fracture in the above case was caused by a blow from the fist, and the soft parts were injured to a considerable extent, causing irritation to the glands in the immediate neighbourhood of the mouth, and consequent dribbling of the saliva; the gum was also lacerated so that the bone could be seen, thus rendering the fracture a compound one. We lately had a very bad case of fracture of the jaw in this hospital. A young woman was struck with great force on the face by a heavy piece of iron, which stunned her; the lower jaw was fractured vertically, but the fracture also extended horizontally, so as to separate a considerable portion of bone, which afterwards came away. The alveolar

processes of the front of the upper and lower jaws were also broken off, and both lips were lacerated and contused to a great extent. A perfect cure, without deformity, except that arising from the cicatrices of the wounds, was effected.

In the case of Bradley, the displacement was mostly caused by the weight of the bone, and by the action of the muscles, the large portion being drawn down by the action of the hyoid muscles, while the posterior or smaller portion is drawn upwards and inwards by the masseter and pterygoid muscles.

In cases of this fracture pieces of cork are generally recommended to be placed between the teeth in order to keep the fractured portions in good apposition, but in the above case they were not required as his teeth were very regular.

WEST NORFOLK AND LYNN HOSPITAL.

COMPLICATED SURGICAL CASES UNDER THE CARE OF CHARLES COTTON, M.D., F.R.C.S., &c.

COMPOUND FRACTURE AND POSTERIOR LUXATION (?) OF LOWER JAW: MILD CONCUSSION: SUBSEQUENT OTITIS: IMPAIRED MASTICATION AND DEAFNESS: CURE.

John Hockinstone, aged 30, labourer, admitted September 13th, at three p.m. Was reported as having been struck by an iron monkey, whilst assisting in driving piles upon the railway premises. He was greatly stunned by the accident and afterwards became senseless, when he was immediately conveyed to the hospital. On examining the injured parts the lower lip was found cut, and a wound about three inches in length, parallel, but below the chin, leading to a fracture through the symphysis of the jaw, the ends of which were separated and drawn backwards and downwards within the mouth, and somewhat overlapped. The incisor teeth were loosened and the central ones displaced. Rather profuse bleeding from the auditory passages was observed, and some puffiness and swelling around and immediately in front of each ear. On moving either ramus of the jaw the hæmorrhage from the corresponding ear was much increased, and a squashy sound produced. The condyloid processes were extremely mobile and gave a grating sensation, but no distinct crepitus could be detected. The mouth is half open and some blood appears to come from the back of the fauces. The eyes are suffused from congestion; the surface cool; pulse weak, 96; and the man, though roused by the examination, is still somnolent, listless and heavy.

Hair removed, cold applications to the head and ears, hot bottles to the feet. The patient was placed in bed in an upright position, to allow the jaw to fall forwards, as it was found useless to attempt any further adjustment of the fracture. A drastic purgative enema to be thrown up, should more aggravated cerebral symptoms supervene.

14th. Passed a restless dreamy night; is now quite

* Œuvres Chir. de Dessault, par Bichat, tom. i., p. 180.

rational; the face and injured parts are much swollen; the bleeding from the ears, excepting a trifling oozing, has ceased; pulse feverish. Allow only cold water for diet and continue the applications to the head.

15th. Features much distorted from the swelling above and below the angles of the jaw; articulation indistinct; swallows a little water with the greatest difficulty; the breath is very fetid, and there is a constant dribbling of saliva; pulse weak. Pergat, and give milk in lieu of water.

16th. Cannot sleep; is continually conghing; cold applications to be discontinued. Habeat. Syrup. Papav. Coch. parvum tussi urgente.

18th. Swelling subsiding; cough less; feels pretty easy; bowels acted; there is an offensive sanio-purulent discharge from the wound; the oozing from the ears has ceased.

19th. Bad night; much pain in the ears. Apply hot fomentations.

20th. Much bloody discharge from the ears followed the use of the fomentations, giving considerable relief. The left ear is still in pain and clogged with blood. Arrowroot, broth, or milk diet.

22nd. Sleeps well; œdema of, and discharge from, auditory passages.

26th. Sanious matter from the ears; swelling of the face greatly subsided; silver plate adapted to the jaw and bandage applied.

29th. Delirious during the night; excruciating pain in the right ear. Leeches and hot fomentations applied. To be purged.

30th. Quite easy and comfortable owing to the ears discharging freely.

October 12th. Wound below the chin healed; breath still very offensive, and much dribbling. Apply with a feather frequently, a linctus of honey and myrrh.

Nov. 30th. The mouth admits of being opened to the extent of a quarter of an inch. There is but little irregularity of the fractured symphysis, and union is complete. The articulating processes of the jaw are ankylosed, and the soft parts around are stiffened and consolidated. Considerable purulent weeping continues from the ears, and deafness. Slop diet. Use frequent friction and gentle attempts to open the jaws. Made out-patient.

Dec. 17th. In-patient a few days. Pain and profuse discharge from the ears and increased deafness. The teeth can be separated so as to admit of the end of the finger. *Admoveantur hirudines, iij., sub sing. aures.* Hot fomentations; solution of ox gall to be dropped into the ears daily. To desist from further attempts to move the jaw.

February 23rd, 1848. Discharge from the ears diminishing; much less deaf; can open the mouth to nearly its natural extent; but there is no lateral motion of the jaw.

March 24th. No running from the ears; hearing but slightly impaired. Is regaining daily the power of mastication. Discharged cured.

The bleeding from the ears, extreme mobility of the condyloid processes of the jaw, and other symptoms

manifested at the time of the accident, led to the conclusion that in addition to the compound fracture of the symphysis, dislocation backwards of the jaw had taken place by *contre coup*, and through the yielding of the front walls of each bony auditory meatus, a diagnosis which was rather confirmed than disproved by the ankylosed condition of the jaw which followed, and the frequently recurring attacks of internal otitis. The termination of the case under simply *dietetic* and cautious antiphlogistic discipline was most satisfactory, and the report has at least the interest of recording a rare though not unique form of surgical injury.

PROVINCIAL

Medical & Surgical Journal.

WEDNESDAY, MAY 30, 1849.

THE Anniversary meetings of the parent and various branches of the Association are always regarded with more or less interest by its members, in all parts of the kingdom.

We cannot do better, we think, than take the period which now presents itself as a fitting moment to draw attention to the great and practical benefit which these meetings are capable of producing, if viewed in a proper light, and taken advantage of in a spirit of truthful research.

The Provincial Medical and Surgical Association was established with a two-fold object; that of promoting sociable intercourse among the various members of the profession, and that of making that profession worthy of its high calling, by the cultivation of medical science, and the dissemination of sound views of medical practice. That the first object has been fully gained, we think we may fairly call upon the experience of the past to prove; that the second object has, to a certain extent, also been carried out, we are equally sure; but it is just because we think that much more may be done, that we venture to suggest our future records may be made still more conducive to the absorbing interests of science.

It has always been the opprobrium of our art that its principles are, more or less, unsettled; that we cannot reduce our data to the exactitude essential to the establishment of unvarying rules of practice, and thus place medicine among the sciences strictly called inductive. This is partly owing to circumstances which are beyond our control. The human body varies in its constitution with each individual, and so must

necessarily its diseases, and their treatment also. But much of this apparently inherent defect in the basis of our science depends upon the want of co-operation among ourselves,—in the observation, registering, and enunciation in a succinct form, of facts. It is a pleasing illusion for an active mind to build up beautiful theories of disease, but if the basis of the structure is not sound, it not only tumbles down about his own ears, but it more or less injures the whole fabric of medical science in its fall.

We cannot illustrate this remark better than by referring to the *results* of the various theories which marked the schools of medicine during the latter part of the last, and the beginning of the present, century. One class of men referred the origin of disease to the solid structure of the body, and were therefore termed Solidists; another to the fluids, who were, *par excellence*, Humorists. One party located the origin of fever in the intestinal tube; another with equal confidence in the brain. Here we find men of education and eminence advising and practising large bleedings in fever and rheumatism; there equally clever advocates condemning the practice as injurious and fatal. Nor are we in our own times free from much of this dangerous and humiliating trifling. The cholera has just been desolating our shores. We find our able men not only advocating, but bringing strong proofs, of the value of small doses of mercury, as a sure remedy in the disease; another condemns the practice as injurious, and argues that the disease is an ague, and treats it with quinine. Chloroform here; acetate of lead there. Bleeding from the feet into a hot bath was specific in Persia, and fifty other remedies have been equally successful in various parts of Great Britain. Well: cholera has, we hope, left us. Are our principles of treatment one iota more settled than they were? We fear not. And why? Simply because facts have been disregarded, the experience of others neglected, and the utter want of a rational system of observation and comparison of the effects of what we know, which has been manifested by those in authority, during the late epidemic. As a contrast to this unsatisfactory statement, let us turn for a moment to an opposite picture.

If an educated medical man of the present day is consulted in a case of suspected disease of the lungs, he examines the subclavicular region;

if he finds no dulness on percussion, and the breath sound normal, he pronounces at once that the individual is not phthisical. It is true there may be rare exceptional cases, but in these the symptoms are generally clearly indicated, and they are so rare that a man may pass the best part of his life without meeting with one. It is impossible to overrate the value of this diagnostic law. How many a fear has its knowledge dispelled? Nay, how often, by driving away fear, has it prevented that wear and tear of mind—that constant dread which we know to be favourable to the formation of tuberculous deposit? And yet this fact we owe to the untiring energy,—the zeal,—the profound and philosophical exactitude of one man. The name of Louis must ever remain indelibly connected with the progress of medical science in the nineteenth century. But of this very disease there is still much to be learned. After ages of hopeless research, we have been lately startled with the announcement that a remedy for phthisis pulmonalis has been found.

We have the authority of an eminent physician, a worthy pupil of the school of Louis, that consumption of the lungs has been cured, and that “every day’s experience increases his astonishment at the effects produced by cod-liver oil in catalectic deposits.”*

Now, here is a subject worthy of attention for an Association which numbers among its members so many men capable of entering into the enquiry, whose practice will give them the means, and whose love of their profession the will and the spirit, to carry it out. The—alas! sole remaining Editor of this Journal, has undertaken to conduct this enquiry, with the assistance of the members of the Association. Let us urge upon those who attend the approaching meetings, not to lose sight of this important investigation. Desultry information will be of no value: every particular in registering the facts must be noted down clearly—the name, age, sex, temperament, hereditary tendency, stage of disease, previous history, present condition, physical and general symptoms, progress of the case, with every particular of treatment, must be noted down, and the results, under any circumstances, will prove a most valuable report upon the disease.

It is undoubtedly true, that the habits and pursuits of many members of the profession are

* Dr. Williams’s “Principles and Practice of Medicine.”

not calculated to assist in investigations of this kind. They are too much occupied with the business, or even, often, with the pleasures of life, to devote any time to pursuits of a literary character; but if nineteen out of twenty—a proportion, we think, quite beyond the mark—are of this class, if every twentieth member of the Association will enter *con amore* into this investigation, or others of a similar character, we shall have the united practical observations of nearly 200 practitioners in different localities throughout the kingdom. We have no hesitation in affirming that a report produced from such materials, and extending over one or two years, would be the most valuable document ever devoted to the interests of science and humanity.

Review.

On Cancerous and Cancroid Growths. By JOHN HUGHES BENNETT, M.D., F.R.S.E., &c. Edinburgh: Sutherland and Knox. 8vo. pp. 260. With One Hundred and Ninety Illustrations, copied from Nature, and Drawn on Wood by the Author.

Dr. Bennett believes that the only method of lessening the uncertainty that prevails with regard to the nature, diagnosis, and treatment of cancer, is careful investigation into the clinical parts of each case, conjoined with an accurate and minute examination of the morbid growth. In the present work the symptoms and exact appearances of the cancerous structure, as seen by the naked eye, as well as under the microscope, are given in fifty-six cases. Each case is illustrated by one or more wood-cuts, which, in order to insure correct delineation, were drawn by the author himself, and cannot but be of great value to all those who are desirous of studying the minute structure of morbid growths. The description of these cases, with short commentaries, which serve to point out the particular facts of interest contained in each, constitutes the first part of the work. The second part consists of a systematic account of cancers derived from original observation, as well as from the writings of all the modern English, French, and German writers on the subject.

At the commencement of the first part the author gives some very useful instructions as to the manner in which morbid growths should be examined with a microscope, and by means of re-agents. Such examination always necessitates great skill in manipulation, considerable time, and knowledge of pathology, and no one can read the account of disease given by Dr. Bennett without feeling satisfied of the uncommon pains he has taken with this part of the book.

The term *CANCEROUS* is employed by the author to denote that morbid growth which pathologists comprehend under the term *scirrhus*, *encephaloma*, and *colloid cancer*, and in which nucleated cells infiltrated among the filaments of a fibrous stroma are always found. The word *CANCROID* is, following Alibert, used to denote those various kinds of lesion which more or less resemble cancers to the naked eye, which are continually mistaken for them by practical men, and yet do not correspond with them in structure. These are enumerated under the heads of *fibro-nucleated*, *epithelial*, *fibrous*, *cartilaginous*, *fatty*, and *tubercular* *cancroid* growths.

The fifty-six cases described in the first part of the work contain instances of cancerous growths in most of the textures and organs of the body, as well as of the several *cancroid* growths above enumerated. Not a few of these presented specimens of the same lesion, more or less modified in various parts of the frame. Some forms of cancerous and *cancroid* structure are here described for the first time; among these may be mentioned (*Obs. vii.*) a peculiar tumour removed from the breast by Mr. Page, of Carlisle; *Obs. ix.*, a fungoid tumour of the bladder; *Obs. xxi.* to *xxiv.*, or four cases of *cancroid*, or fibrous hypertrophy of the stomach, hitherto considered as *scirrhus*; *Obs. xxxi.*, cancer of omentum and peritoneum loaded with calcareous deposit; *Obs. xxxii.*, a supposed cancer of the brain, which proved to be tubercle; *Obs. xxxiii.*, a peculiar *cancroid* tumour of the tentorium; *Obs. xxxiv.*, *xxxvi.*, and *xlvi.*, illustrative of a new kind of growth, called by the author *fibro-nucleated*; and, *Obs. lvi.*, an epithelial ulcer of the tongue. This part of the work contains descriptions of morbid growths of the female mamma in ten cases; of the testicle in two cases, of the uterus in five cases; of the stomach and pylorus twelve cases; of the lung in one case; of the duodenum in two cases; of the rectum in one case; of the omentum in three cases; of the parotid gland and neck in four cases; of the brain in two cases; of the bones and muscles in eight cases; and of the integuments, face, lip, scrotum and extremities in other cases. There are four cases of epithelial cancer, three of *enchondroma*, and five of *colloid cancer*. One of these latter (*colloid* of the peritoneum) is much more extensive than the case lately published by Dr. Ballard, in the "Transactions" of the Royal Medical Chirurgical Society of London.

The author has taken pains not only to describe each of these cases in a most accurate and minute manner, in the triple relation of symptoms during life, *post-mortem* appearances, and minute structure of the morbid growth, but he has carefully given figures of the latter in every instance, feeling assured "that no mere verbal description of ultimate tissues is sufficient to communicate correct impressions of them to others." Many cases are illustrated by four or five figures, and

one contains seven. These illustrations give a particular value to the work, and we agree with the author in thinking that they will be most useful to the surgeons of this country as a guide to the structural differences in cancerous and canceroid growths. But, as a more detailed analysis of the cases themselves without these illustrations would be very imperfect, we pass on to the consideration of the second part of the work, in which is given a systematic account of cancers, partly founded on original observation, and partly from the accounts of others.

Dr. Bennett treats the subject of cancerous and canceroid growths under the following heads:—1, histology; 2, chemical composition; 3, general anatomy; 4, pathology; 5, statistics; 6, diagnosis; 7, prognosis; and 8, rational treatment.

I. HISTOLOGY.—The different cancerous and canceroid growths contain the following elementary forms:—1. Molecules and granules. 2. Naked nuclei. 3. Cells of various kinds. 4. Filaments or fibres. 5. Blood-vessels. 6. Crystals. These are the elementary forms of all morbid products, nor is there anything characteristic of cancer in either of them when viewed alone. It is only in relation to each other they become important.

1. *Molecules and Granules.*—By the term *molecule*, is understood a minute body in which no determinate external edge and internal centre can be discovered. By *granule* is meant a body which varies greatly in size, and is distinguished by possessing a distinct shadowed ring or margin, the external edge of which is abrupt. The distinction between molecule and granule is only referable to size, and the magnifying power with which they are viewed. These bodies vary in composition and shape, and are formed by precipitation and by disintegration. They may be produced mechanically, and have distinct movements of their own. The author considers that they constitute the real basis of all the tissues, and not the cell, as maintained by Schwann, or the nucleus, as is contended for by Henle. "No cells" he says "are formed without nuclei, and no nuclei without granules; and it is a knowledge of the laws regulating the disposition of the latter in an exudation, and within nuclei and cells, that must guide us to rational therapeutics, so far as the diseases of nutrition are concerned."

2. *Naked Nuclei.*—The nuclei formed in cancerous and canceroid growths are produced in the same manner as similar bodies in other textures, and may be primary or secondary. Dr. Bennett, however, points out that there are some growths, which he calls fibro-nucleated, entirely composed of fibres and naked nuclei. Such growths have even the power of returning after excision—a circumstance not considered by him as any proof of malignancy. On the contrary, he gives cases which satisfactorily show that some tumours may occasionally return consisting of a single blastema, with the earliest traces of commencing structure; others, when organization has proceeded so far as to constitute a fibro-nucleated texture; a third class, where perfect cells are formed; and a fourth, where the whole consists of fibres. Naked nuclei are not peculiar to cancerous formations, and whether they possess the power of

re-development, like cells, is unknown. No part, however, shows that they are capable of spreading into, and giving rise to morbid growths in neighbouring textures.

3. *Cells.*—Although there is no kind of cell formation which at all times, and under all circumstances, is capable of being distinguished from any other form of cell growth, great differences exist among them, the study of which is most important in distinguishing one tissue from another. In cancerous and canceroid growths, the following cells have been observed:—1. The cancer cell. 2. Epithelial cell. 3. Cartilage cell. 4. Compound granular cell. 5. Fibro-plastic or fusiform cell. 6. Pus cell. Dr. Bennett gives a lengthened and minute description of each of these, during which, he continually refers, in illustration, to the numerous figures with which the first part of the work, and this chapter, are abundantly supplied, and without which his description would be unintelligible. The following is his account of the differences existing between cancer and epithelial cells:—"It is important to know that a young pavement epithelial cell, when isolated and viewed by itself, presents all the physical characters of a cancer cell. This is especially the case when they have been lying some time in serum or other fluid, as often occurs with the cells lining the air vesicles of the lungs, the ventricles of the brain, the mucous coat of the bladder, &c. When studied, however, in mass, nothing can be more easy than to distinguish them. They have a disposition to run together in groups, to adhere at their edges, and are of tolerably uniform size. Cancer cells, on the other hand, never exhibit a tendency to run together in groups, but are for the most part separated by a greater or less quantity of molecular and granular matter, either disintegrated, or aggregated together. They never adhere at their edges, and vary greatly in size. As epithelial cells become older, their dissimilarity becomes greater. They are then flatter, and resemble scales. They are also more opaque and more resistant to the action of acetic acid."

4. *Filaments and Fibres.*—Fibrous tissue is supposed to be formed in three ways—1st, by the precipitation in a fluid blastema of fibrinous molecules in the form of rows, which afterwards melt together, and become consolidated into filaments. 2nd. By the accumulation of granules, so as to produce by their uniting together a spindle-shaped nucleus, which, by its elongation, splits up the coagulated exudation into laminae and fibres, as is observed in many forms of fibrous tissue. 3rdly. By the formation of a cell, (fibro-plastic cell,) which becomes elongated at both ends to form a fusiform corpuscle, which ultimately splits up into filaments. All these modes of formation are well observed in different cancerous and canceroid growths.

5. *Blood-vessels*, and, 6. *Crystals*, present nothing peculiar in the structures under consideration.

II. CHEMISTRY.—All that can be determined from the few analyses of cancerous and supposed cancerous tumours that have been made is, that they contain the same constitutional elements as other forms of exudation from the blood, and that it is impossible to distinguish these, chemically, from other morbid products, or even from healthy tissues. It is not by analysing large masses of morbid structure, that any light will be thrown on the chemistry of cancer; but rather by separating, with the aid of the microscope, the minute

structural elements entering into the composition of the growth, and then endeavouring by chemical manipulations under the same instrument, to ascertain the exact nature of each. In this way histologists are enabled to separate the chemical principles of cancerous and cancroid growths into four groups, viz.,—1st, albuminous; 2nd, fatty; 3rd, mineral; and 4th, pigmentary principles.

Albumen constitutes the basis of the fibrous element found in morbid structures. The author brings forward numerous arguments to shew that fibrin is formed from albumen, and that its occasional increased amount in the blood is an effect, rather than as some have supposed, the cause of so-called inflammatory diseases. The albuminous principle once coagulated in the form of molecule, fibre, or membrane, is rendered more transparent by acetic acid. This property of acetic acid is a very valuable one for the histologist, he is thereby enabled to give transparency to thin sections and filaments, and partly dissolve cell walls.

Fatty matters may exist chemically in cancerous and cancroid growths under four conditions, that is,—free, saponified, non-saponifiable, and as fatty acid. Structurally, it is never free; for, being invariably associated with fluid albumen, no sooner is oil precipitated so as to assume form, than the minutest granule of it becomes enclosed in a thin coagulated film of albumen. Such granules disappear on the addition of æther, and their number is a tolerable index of the amount of fatty matter present. Fat may enter the body ready formed in the food, and it may be produced in the system from changes which occur in starch, gum, sugar, &c. It is also probable that the albuminous principles may be converted into fat, of which the presence of compound granular corpuscles in old exudations is the most common evidence. Fat, probably held in solution, enters the walls of previously-existing cells by endosmosis, and is precipitated in the form of granules, which become enveloped with a layer of albumen, and are prevented from passing out. Hence various kinds of these bodies act as mere storehouses for excessive formations of fat in morbid growths, as the adipose cells proper perform the same function in healthy tissues. The conversion of muscular fibrillæ into fat may be seen to take place under the microscope, independent of cells or nuclei.

Mineral principles are not uncommon in cancerous and cancroid growths, and occasionally they also enter pre-existing cells in a state of solution, and become afterwards precipitated, so as to assume somewhat of an organized appearance, of which a very remarkable instance is given (Obs. xxxiii.) in a case of tumour attached to the tentorium.

Pigmentary principles are all derived from the blood. The black pigment found in melanosis is accumulated within cells, and disappears on the addition of nitric acid or chlorine, whilst that which accumulates in the bronchial glands and lungs of old people, and in the black phthisis of colliers, does not. In the latter case the black substance is undoubtedly carbon; in the former its nature is unknown.

III. GENERAL ANATOMY.—The author agrees with Dr. Walshe in thinking that there are only three forms of cancer properly so called,—namely, scirrhus, encephaloma, and colloid, of each of which a descrip-

tion is given. The cancroid growths we have already enumerated, and these are also described with the aid of numerous figures. Want of space prevents our following the author through this chapter, although we recommend it to the perusal of our readers, especially the remarks on epithelial cancroid growths.

(To be continued.)

COD-LIVER OIL IN PHTHISIS.

DR. RANKING'S INQUIRIES.

The points to which Dr. Ranking would respectfully direct attention are—

Number of cases, successful and unsuccessful.

Stage of the disease in different cases in which it was exhibited, as marked by the physical signs.

Degree of amendment produced, and its duration.

Quality, dose, &c., of the oil.

General effects as regards diminution of night-sweats, expectoration, and increase of weight, &c., &c.

Any other information deemed valuable.

Torquay, May 18th, 1849.

Dear Sir,—During a visit to Edinburgh in 1845, the late Dr. William Campbell pointed out to me the efficacy of cod-liver oil in scrofula, rachitis, and the debility which often follows dentition in children. I repeated my visit the following year, when the practice was confirmed by that accomplished physician, and accurate observer, Dr. John Hughes Bennett, who also kindly showed me numerous cases of bronchitis and of reputed consumption in which it had been employed successfully, as well as many specimens of disease of the lungs, in which cavities had become perfectly consolidated under its use, the patients having died of other diseases. Amongst many others was a remarkable instance of a man, who had been thus treated formerly in the Edinburgh Infirmary, and who had died four years after of compound fracture of the leg in the same Institution. I had prescribed it many years ago in chronic rheumatism, but I was not previously aware of its having been employed in diseases of the lungs, and others of defective nutrition.

On my return to this place, I found on enquiry, that it had been occasionally but rarely given, and shortly afterwards I published a paper in the Journal, directing the attention of the profession to its administration in certain cases. During the following winter numerous opportunities of testing its efficacy offered, and it was presented in a variety of cases with decided benefit, and in one especially, in which the existence of a tuberculous abscess was satisfactorily ascertained by repeated careful examinations with the stethoscope, to such an extent as to render recovery almost hopeless. This patient was weighed, and the limbs were measured, before it was exhibited; the experiment was repeated the first day of every month. At the expiration of the first month a sensible improvement was manifest in the

weight and size of the limbs. This amendment was progressive, but after some time an unfavourable change was observed, the weight and size diminished, and the cough and expectoration increased. On close investigation it was discovered that a different oil had been substituted for that originally given, and on returning to it a speedy restoration to the former favourable state followed, and the patient gradually increased from five stone to eight stone six pounds, all the other symptoms which had so justly alarmed the friends having disappeared. The recovery has been confirmed by a residence in this mild climate during the last three winters, and the patient is now in the enjoyment of robust health.

Not having kept a register of cases I cannot furnish all the details you require, but the oil will be found most efficacious in bronchitis, and in cases of cough, with copious expectoration, accompanied with emaciation and night sweats, and where no derangement of the bowels existed. One table-spoonful three times a day will generally be found a sufficient dose for an adult, although, in some cases, a larger quantity may be taken with advantage, and I well remember an instance in which four ounces were taken daily for a long time, with marked benefit. I have always used the Scotch oil, which is manufactured at Leith, and supplied to the chemists in this town by Duncan and Flockhart, of Edinburgh. The duration of its employment must depend on the case, and the judgment of the physician; it may be advantageously suspended sometimes, and preparations of steel usefully substituted in its stead, and sometimes both remedies may be judiciously conjoined.

To give some idea how generally it is prescribed, I enquired of the nine chemists in this place what quantity of the oil they had sold from the first of November last to the first of April, and I found that one had disposed of forty gallons, and had nearly exhausted ten on hand; another twenty-two gallons; and the third sixteen, besides other oil obtained from London, which some preferred. I conclude, therefore, that so large a quantity of a remedy, not of the most agreeable kind, would scarcely have been consumed in a small locality, unless it had been found beneficial, and I observe that some of my medical brethren, who at first were prejudiced against it, and deemed it a species of quackery, averring that they could not prevail on their patients to swallow so nauseous a dose, had prescribed it freely, and find to their astonishment, that patients rarely make any serious objection to it.

The following case is an example of the beneficial exhibition of cod-liver oil:—

I was consulted by a gentleman nearly twenty years since, who had lost two brothers in consumption, and whose symptoms were so threatening as to excite very great apprehension for his safety. He had gradually been emaciating for some months, with slight cough, hoarseness, and some ulceration of the throat, attended with much debility. Under general treatment and careful attention he slowly recovered, and continued in good health until a year ago, when he became alarmed at

the return of some of his former symptoms. His appetite and spirits failed, and he suffered so much from irritation in the throat, as to oblige him to give up his duty in the church. As there was nothing in his case to forbid the use of the oil, I advised him to give it a full trial. He began to take it in June last, and in the following January he wrote to tell me that he soon experienced its good effects, that he had quite recovered his voice and strength, and that he had increased fourteen pounds in weight. He also added that he had given it to many of his poor neighbours in scrofula, and other diseases of weakness, with much benefit.

In conversation with Dr. Williams on the subject, he remarked to me, that a week scarcely passed in which the oil did not reveal miracles to him.

JONATHAN TOOGOOD.

To Dr. Ranking.

Proceedings of Societies.

BIRMINGHAM PATHOLOGICAL SOCIETY.*

February 1st, 1849.

W. H. PARTRIDGE, Esq., in the Chair.

DISEASED PLACENTA, CONTAINING AN APOPLECTIC EFFUSION.

Mr. F. Elkington related the following particulars of this case:—

December 30th, 1848. I was requested to visit Mrs. H., who states she has been out of health for nearly twelve months. She is 32 years of age; has been married twice; to her present husband about two years. Had two children by her first husband, but none since her last marriage. Has had a constant vaginal discharge for some months, and an aching in the back, hips, and thighs; at times also a pain from sexual intercourse. Her appetite has been bad; bowels costive. She was unwell August 3rd; ceased to be so on the 4th; she returned home from a month's visit on the 5th or 6th. Shortly after her return to her husband, she fancied she was pregnant; had the same symptoms she had had in her former pregnancies, and gradually increased in size up to the 2nd or 3rd week in December. She did not menstruate after August, but had been regularly unwell up to that time. About the 15th of December she walked several miles, after which she was a good deal fatigued, and felt a weight at the lower part of the abdomen. The leucorrhœal discharge was slightly coloured, and more profuse. From this time she lost all symptoms of pregnancy, her bosom got softer and smaller, and her figure much less. The vaginal discharge was copious and constant, and of a dirty yellowish colour.

December 31st. The bowels have been freely moved; she is very thin; tongue clean; pulse feeble; the breasts are small and flaccid; there is no areola around the nipples. The abdomen is small; the uterus cannot be felt by external examination, except when the ends of the fingers are pressed down behind the pubis.

* Continued from page 272.

Examination per vaginam.—The vagina is relaxed; the os uteri puffy; the anterior aspect of the cervix enlarged; the body of the uterus is enlarged generally, more especially so anteriorly, but there is none of the hardness of disease communicated to the finger. On raising the body of the uterus with the left hand in the vagina, the fundus uteri can then be distinctly felt with the fingers of the right hand externally.

Examination with the speculum.—A large quantity of muco-purulent discharge was occupying the upper part of the vagina. There is extensive ulceration of the os uteri, covering the greater part of the posterior lip, the whole of the anterior, and extending forwards to the cervix. The ulceration looks unhealthy; the granulations pale and flabby.

I told her I believed she was pregnant, but that the child was dead, the vitality of the foetus having been destroyed probably at the time she took such immoderate exercise, the ulceration, which has existed some months, having weakened the foetus. She did not believe that she was pregnant, and said she was suffering from disease only.

She was ordered to take the Tinct. Ferri. Mur. in Inf. Quassiae, bis die; an aperient occasionally. To use a slight astringent injection; to have the Argenti Nitratiss applied to the ulcer twice a week. To observe the recumbent position, &c. &c.

January 20th, 1849. She has progressively improved; the ulceration is smaller, and more healthy looking; the discharge less. On making a digital examination to-day, I thought the uterus had increased in size since my first examination, and on that account suggested the possibility of the foetus being still alive, and that she had not become pregnant so soon as August. She replied she was now confident she was not pregnant.

31st. When I paid my usual visit this morning, she informed me she had miscarried; that the day before, after going down stairs, she had slight pains, which increased in the evening, and at length the foetus and placenta were expelled. The foetus was small and shrivelled, but probably, at least, a four months' foetus. The placenta was small, hard, and pale; on the maternal surface was seen a long fissure, and on separating its edges a large coagulum embedded in the substance of the organ. This was not seen until the edges of the fissure were separated. From the appearance of the foetus, and especially of the placenta, it is probable that the clot was formed after taking such a long walk, and that the ulceration of the os, by keeping up a congested and morbid state of the uterus, had acted as a predisposing cause.

February 23rd. Ulcer nearly healed, but there was still two spots of ulcer, each about the size of a pea, on the anterior lip. The uterus and cervix have regained their normal character.

LARGE FLESHY TUMOUR OF THE PELVIS, SERIOUSLY OBSTRUCTING DELIVERY, WHICH WAS EFFECTED BY THE AID OF CHLOROFORM: DEATH ON THE SIXTH OR SEVENTH DAY.

Mr. F. Elkington presented a preparation removed from a lady who died about seven days after delivery.

He saw her, in consultation with the gentleman who regularly attended her, for the first time, August 19th, 1848, when he took the following notes of the case:—

She is forty years of age, short, has had four children, and was confined of the last in August, 1847. An arm presentation. Child still-born. About a fortnight before her confinement, in 1847, as she was walking down the garden, she caught her foot against a clothe's line, which was lying across the walk, and fell upon her face. The left side of the abdomen was much bruised, and painful for some days afterwards. She recovered rapidly after her labour, and remained well for some months. She menstruated last in April; at the end of the month she thought she was pregnant. In July, whilst busily occupied in the kitchen, below stairs, she heard one of the children, who was up stairs, suddenly scream out, and she ran very quickly up stairs, to the top of the house; in doing so she says she felt as if something inside her had turned over. From that time she had pain in the left side, a difficulty in passing her water, always greatest in the morning, with a frequent desire to do so. She perceived a small tumour, about the size of an egg, in the left iliac fossa, soon after she ran up stairs, which she says has continued ever since, and been painful on pressure; has not been able to lie on that side; has had weight and bearing-down. These symptoms have continued more or less ever since. A fortnight ago she had a slight discharge, it almost immediately went off again.

On Tuesday last, August 15th, she went to a wedding, and in the evening danced. On Thursday or Friday she had diarrhoea, from imprudent diet, all the symptoms increased, violent paroxysm of pain, bearing down, &c. She considered herself in labour, and sent for her surgeon, who found her suffering agonizing pain, and after making an examination, concluded that she had retroversio uteri. He passed the female catheter, drew off a small quantity of urine, and gave her twenty-five drops of Liquor Opii; I saw her a few hours after; she had passed a little urine several times; she had still frequent paroxysms of pain, but they were not so severe. Pain in the sacrum; weight and bearing down. She said she had quickened, and had felt the child several times.

On examining the abdomen, I found on the *right* side, about midway between the spine of the ilium and the umbilicus, a swelling the size of a cricket-ball, distinctly circumscribed, and apparently unconnected with either the bladder or the uterus. The left side and front of the abdomen was entirely free from any swelling. On examining per vaginam the uterus was found very low in the pelvis, the os thrown above the pelvis, and could scarcely be felt. On the left side of the pelvis the uterus was pressed so low down, that the finger could not be passed in *that* direction; it was on a line with the outer edge of the ramus ischii. In the right side of the pelvis there was more room, allowing the finger to pass up between the uterus and side of the pelvis. The rectum was not much pressed open; the uterus appeared chiefly to be thrown to the *left side*, and to the front of the pelvis. A male elastic catheter was passed, and a small quantity of urine drawn off; afterwards the bowels were freely opened by castor oil. She was ordered to keep in bed, and to rest at times upon the elbows and knees.

20th. Has had the bowels well opened by castor oil; passed water several times, and with less pain. Has had a good night without any opiate. The external swelling is a little altered in character, it is not so distinctly circumscribed, feels softer, and can be traced down into the pelvis, as if it were connected with the uterus. The position of the uterus much the same. An attempt was made to raise it, but without success; it was slightly moveable, appearing to yield a little to pressure.

As there is no constitutional disturbance, and but little local suffering at the present time, we think it will be advisable to avoid any active interference, but to watch her carefully. I did not see her again till she was in labour.

Sunday, December 3rd. I was requested to visit her again; I found she had been in labour some hours. Dr. ——— informed me she had on Tuesday a sudden attack of severe pain in the right iliac region, followed by a smartish attack of fever; the membranes ruptured the following day, (Wednesday,) and she has suffered pains, more or less, every day. He had made several examinations during the week, and found the os uteri high up, but sufficiently open to admit two fingers. She was taken worse this morning (December 3rd) about four o'clock, at which time labour appears to have commenced. There was little or no advancement till 7 or 8 p.m. The pelvis was nearly occupied by a tumour, which prevented the descent of the uterus. About 8 p.m., whilst Dr. ——— was sitting down stairs, both arms suddenly came down; previously he had not been able to ascertain the nature of the presentation. He introduced his hand immediately, and succeeded in getting hold of one foot, but experienced so much difficulty and resistance in bringing it down, that he abandoned the attempt. In making the attempt to turn he had pushed up a great part of the tumour out of the pelvis. At my next visit, 9 p.m., she was feverish, anxious, and excited; pulse quick; both arms were down; the left knee could be felt above the pelvis; the foot had slipped up out of reach; the tumour still occupied the back-part of the pelvis, but the greater portion of it was now felt externally above the pelvis and right ilium; it was firm, and inelastic in character. The uterus was irregular, high up, and firmly contracted upon the child; the pains were frequent and severe.

She was supposed to be not more than eight months advanced in pregnancy, and although the child was probably a small one, still with a large tumour in the pelvis, the peculiarly awkward position of the child, and the contracted state of the uterus, there appeared to be little probability of turning being effected with safety. We determined, however, to try the effect of chloroform, and whilst she was under its influence, to make an attempt to bring down the knee; this was fortunately readily accomplished, the breech soon followed, and delivery completed in a few minutes.

On making an examination after the expulsion of the foetus, the whole of the back part of the pelvis was found to be occupied by the tumour, and the posterior wall of the vagina in an unhealthy state. After delivery there was great prostration, frequent vomiting, and a quick feeble pulse, with great restlessness. She was ordered to take a pill, with two grains of opium, every four or

six hours, and about every three hours a dose of mixture, consisting of Mist. Camph. Ammon. Carb., and Acid. Hydrocyan. As I saw her only once or twice after delivery, I am not able to say much about the symptoms or treatment after delivery.

4th, 10 a.m. She was not so restless; had dozed a little; passed urine twice; pulse 120; had vomited less frequently. She had taken only one pill and one dose of mixture. 5 p.m. Pulse 110; vomited only once since last report; very little lochial discharge; she still complains of severe pain in the right hip and iliac fossa. She gradually got worse, and died on the sixth or seventh day.

I was kindly invited to be present at the *post-mortem* examination, made December 11th. We found agglutination of all the abdominal and pelvic viscera; adhesion of the omentum to the uterus; a large sac in the right iliac fossa, ulcerated, and in a sloughy state, and communicating with the upper part of the vagina; the right side of the uterus, below the insertion of the round ligament, was also in a sloughy state; there was pus in the cellular tissue of the pelvis, and about the intestines; there was also some blood extravasated into the cellular tissue of the back part of the pelvis.

The tumour, together with the uterus, vagina, and bladder, weighed nearly four pounds and a half. The tumour measured six inches by four, and nearly three inches deep; it was hard and irregular on its surface. On making a section of it we found that it was made up of irregular and partially-developed cysts, some being cartilaginous, others of a softer texture. It was situated behind and below the peritoneum, placed between the rectum and vagina, and occupying the greater part of the pelvis. The vagina was very much elongated, and at its upper part, and on the right side, it was sloughy and ulcerated, commencing with the cavity or cyst in the right iliac fossa. The right ureter was traced over the anterior surface of the tumour. The ovaries were both atrophied.

I have little to offer in explanation of the cause or origin of the tumour. I think it probable that the nucleus of it was formed by an extravasation of blood at the time she fell down during the pregnancy preceding the one which proved fatal, the coagulum becoming organized, but for a time remaining inactive. When she again became pregnant a stimulus was communicated to the nucleus, which, together with the increased vascularity of all the surrounding parts, hastened its growth, and contributed to its rapid development.

General Retrospect.

SURGERY.

REMOVAL OF A DISEASED OVARY: CURE.

By Dr. Vaugiraud.

This is the first case of operation performed in France; it has proved successful, and may, we trust, give more popularity in this country to a mode of treatment which Dr. Clay's cases have rendered familiar to English surgeons.

CASE.—*Previous History.*—T. R., aged 25, men-

struated at 18; had enjoyed very good health until the year 1842, when the abdomen became enlarged and the menses irregular. These symptoms disappeared suddenly, and during fifteen months the patient did not suffer any relapse; but, at the expiration of that period, the abdomen became distended, and the menstruation deficient. On May 11th, 1844, paracentesis was performed for the first time, and twenty-five litres of transparent fluid having been removed, an ovarian tumour, of the size of the hand, was detected in the left iliac region. From that period forward, the dropsical collection formed with such rapidity and abundance that three days before operation paracentesis was again performed for the fifty-first time. Examination through the abdominal parietes indicated the presence of an oval tumour, extending from the left iliac fossa to the right hypochondrium; its surface was rough, and the tumour moveable.

Operation.—On the 15th September, 1847, the patient having inhaled æther, insensibility was produced in the space of seventy-five seconds, and an incision, three inches in length, was performed to the left side of, and in a parallel direction with, the linea alba; six or eight litres of fluid were permitted to escape, and the length of the incision increased to seven inches. The tumour, of the colour of wine lees, presented itself at the orifice, and, being of a soft consistency, was laid open, in order that its bulk might be diminished by the discharge of a portion of its contents, which were of a serous and puriform character. The pedicle was, as it had been predicted, found on the left side, and was divided, after two ligatures had been thrown round it. Very little blood was lost during the operation, and the wound was united by three sutures.

Progress of the Case.—During the two first days the patient felt remarkably well; she was even permitted to take broth and some wine and water. On the third day the pulse rose to 102, but the digestive functions remained unimpaired, and the intestinal evacuations regular. On the seventh day only the wound was examined; it had healed by primary union, excepting in its most anterior part occupied by the ligatures. On the sixteenth day the threads were removed, and the patient had almost completely recovered twenty-five days after operation.

The tumour weighed nine pounds, and the fluids which it contained were estimated at an equal weight. Its tissue seemed of a fibro-cartilaginous nature, in the intervals of which were found gelatinous, cerebriform, and granular textures. We regret that no chemical analysis of the fluids incarcerated in the growth was attempted, such fluids having been found occasionally to present cholesterine and albumen.

ON THE TREATMENT OF INTERNAL STRANGULATION OF THE INTESTINES BY STRYCHNINE.

By Dr. Homolle.

In this communication Dr. Homolle relates three cases in which he found very minute doses of strychnine (1 milligramme), repeated every hour, completely efficacious, after various other means had been tried in vain in relieving urgent symptoms of internal strangulation,

produced in two of the cases by the return of the hernia *en masse*, and in the other by violent vomiting. It was the knowledge he had of the favourable influence which strychnine exerts upon the peristaltic action of the bowels, in constipation from cerebral paralysis, hypochondriasm, &c., that induced him to employ it in the present cases. The borborygmi, the painless sense of vermicular movement, the rapid cessation of the pain and vomiting, and the expulsion first of gas and then of fæces, which resulted from its employment, confirmed the anticipations he had entertained. M. Amussat, who employs the conjoined force of two or more persons for the reduction of hernia, believes that in this way nine tenths may be reduced; but the taxis is, in point of fact, but the substitution of an external constricting force for the insufficient contraction of the walls of the intestine. The alkaloid by increasing defective, or by correcting irregular, persistaltic action, diminishes the volume of the intestine, and expels the detained fæcal matters, or removes invaginations. It is to be recollected that the obstacle in strangulation of the intestine is hardly ever materially insurmountable. So that this means sometimes may, associated with the taxis, even in strangulated hernia, prevent the necessity of resorting to an operation.—*L'Union Médicale*, 1848, Nos. 138-9, and *British and Foreign Medical Review*, April, 1849.

RETRACTION OF THE LEG: INSTANT CURE BY THE USE OF THE ACTUAL CAUTERY, AND FORCIBLE EXTENSION.

By M. Robert.

Two cases of great interest have been lately admitted into this hospital under M. Robert, of rheumatic affection of the knee, with contraction of the leg, and great pain in the joint, and which was immediately relieved by the use of the actual cautery, the patient having been previously chloroformed. In one case the subject was a robust country woman, about 45 years of age, who had for many months suffered with rheumatism in the left knee. The joint had acquired a great size, and the leg become gradually bent almost to a right angle. After having tried various remedies without any avail, she came to the hospital. On examination the limb was in the position just mentioned, and lay upon its outer side; the knee very large, half as big again as the other, and excessively painful upon the least movement or touch, with inflammatory engorgement in all the surrounding tissues. The patient suffered great pain, and could get no sleep night or day; it was evident that the disease was proceeding either towards complete ankylosis, or towards some other disorganization, from the fact of the abnormal position of the bony surface, and their progressive alteration, as well as of the neighbouring fibrous tissues, and the retraction of the muscles of the leg. M. Robert operated upon the patient in the following manner:—The patient was first placed under the influence of chloroform, and five or six stripes were made about four or five inches in length, with a red hot iron, around the affected joint. M. Robert next forcibly extended the limb, counter-extension

being made at the thigh, whilst the knee itself was acted upon, and the articular surfaces made to return to their normal position. After some effort the limb was brought back to its rectitude and natural length; it was then fixed in a metallic trough, extending from the calf of the leg to the thigh, and the wounds dressed. On awakening the patient found, with surprise, that her leg was extended and fixed in an apparatus. The pains of which she had complained before were gone, and she felt nothing but the smarting of the wounds.

Six weeks after the operation the wounds were healed, and the patient enabled to walk and support herself upon the straightened limb. The knee is still weak, enlarged, but not painful; pressure was applied to it, and the patient gets better and better. The articular movements, though still imperfect, increase more and more, and it is almost certain that in a little while the cure will be complete.

The other case was that of a man 40 years of age, who had long suffered from rheumatic affection of the left knee. The limb was equally bent and painful, as in the former case, though not so much swelled, and the same treatment was adopted in every respect, and with the same satisfactory result.—*Annales de Thérapeutique*, Mars.

REPEATED PUNCTURE OF THE BLADDER.

In the last number we related a case, where, after the day's interval, the bladder was punctured a second time above the pubes, for retention of urine, with stricture. The stricture continued impervious, and the patient died. On examining the body, *post-mortem*, a tumour was discovered in the belly, pressing on the neck of the bladder, which explained the retention, and the insurmountable character of the stricture. There was no effusion round the two punctures into the bladder, nor any suppuration or inflammation, so that one might say the double puncture had occasioned no accident, a fact of some practical interest.—*Id.*

HORNY GROWTH ATTACHED TO THE VULVA.

M. Vaudge relates the case of a female, aged 53, who was the subject of continual and severe pruritus vulvæ. She had, in addition, perceived for some time, a hardness between the labia, which gave her great pain, and interfered materially with her walking. On examination, a large round horny substance, resembling a corn, was found embedded in the mucous membrane separating the labia major from the nymphæ. It was moveable, and was excised without difficulty, when the pruritus ceased.—*Gazette Méd.*, 7 Avril.

MIDWIFERY.

DOUBLE UTERUS: SUPERFETATION.

A female, native of Modena, previously mother of six children, became pregnant for the seventh time in 1817. Nothing unusual was observed, with the exception that the uterus appeared to be unequally distended, a furrow being perceptible along the median line. On the 15th of February, 1817, she was delivered of a male infant at full term and well developed. The placenta was expelled naturally, and the woman

recovered her usual strength, but it was remarked that one half of the abdomen was still enlarged, and the movements of a fœtus could be distinctly ascertained. The patient continued in excellent health until March 14th, just a month, at which time labour ensued again, and she was a second time delivered of a male infant, living and well formed. In 1822 she became pregnant again and bore a child now living.

Various explanations were given of that extraordinary case, and amongst others it was considered as a case of superfetation, with double uterus, by M. Binogli. The justness of this opinion was verified last year by the death of the patient from apoplexy. On examination, the uterus was found to be double, with a single cervix. The preparation is preserved in the Hospital at Modena.—*Encyclograph Méd.*, Fev. 1849.

ON THE EMPLOYMENT OF COLD DOUCHES TO THE UTERUS.

M. Fleury communicated a memoir on this subject to the Académie des Sciences. His observations admit of the following summary:—

1. Cold douches will not cure uterine ulceration directly.

2. They are capable of inducing a revolution of engorgement and hypertrophy of the uterine neck, however chronic and rebellious to treatment they may be.

3. In favouring the revolution of the hypertrophied uterine tissue, cold douches assist materially in causing cicatrization of ulceration.

4. The cold douch will also restore several of the displacements of the womb, for which mechanical contrivances have been required, and becomes in this manner a means of removing sterility.

5. They, by giving tone to the uterus, and to the system in general, prove a prophylactic against abortion.

6. They are the best remedies for pruritus of the vulva and vagina.—*Gazette Médicale de Paris*, Mars. 11, 1849.

BENEVOLENT FUND OF THE PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION.

To W. Newnham, Esq., Treasurer of the Benevolent Fund, &c.

Andover Villa, Cheltenham,
March 21st, 1849.

Dear Sir,—As the time pointed out by you for communicating some proposal for the improvement of the "Benevolent Fund" of the Provincial Medical and Surgical Association is now fast approaching, I think it right to inform you, that in consequence of the continuance and increase of the neuralgic affliction under which I have so long laboured, I have been unable to devote myself sufficiently to the consideration of the subject to allow of my offering with confidence any improvement on the points I ventured to offer for your consideration last year.

I have no copy of the propositions I then made, but

to the best of my recollection the principal object of my recommendation was, to render the fund more useful for the relief and support of the members themselves, their widows and families, under circumstances of distress,—from sickness, death, or other causes, by which means the stimulus of self-interest would be brought into operation, to induce a greater number of the members of the Association to join the Benevolent branch, as it is evident, from the comparatively few of the nearly two thousand members who have as yet come forward for that purpose, that some more urgent motive than that which moved the charity of the “*good Samaritan*” is required.

God forbid that by this suggestion I should mean any portion of the fund, now appropriated for the purely benevolent “two-fold” objects to which the fund has hitherto been applied, should be diverted elsewhere, but on the contrary, by adding the stimulus of self-interest to that of pure Christian charity, to add so much to the fund, as a whole, as would enable the managers to appropriate a portion of it for that purpose more than equal to the sum now annually distributed; but to ensure the success of such a plan, it would be necessary that every member of the Association should contribute to this fund,—*i.e.*, that after a certain date, every member who may join the Association should be expected to do so, as a condition of his admission, but that it shall be voluntary with respect to those already enrolled.

It might be advisable, also, to extend the advantages of the fund still further, and render it more useful to those who, during their lives, may have no occasion for assistance, as the sum raised by so large a number of subscribers would be sufficient to allow of appropriating a certain portion of it to be applied in the manner of the “*Supplemental Fund*” of the Navy Medical Officers, by which every member would be enabled, if he thought proper so to do, to ensure his life for an annuity to his widow or orphan children, according to the calculations of the Swedish tables of the late Dr. Price.

The “*Supplemental Fund*” of the Navy Medical Officers at the present time affords the means of effecting an insurance of that kind at two-thirds of the amount set down in those tables, which is an advantage that many would be glad to obtain.

In order to bring such plan into immediate efficient operation, I should recommend, as I did in one of my letters to you last year, that an appeal should be made at the next general meeting of the Association, to the opulent members, to come forward with such donations as they can afford, for the benefit of those who have been less fortunate, in order that increased benefits from the fund may come into immediate operation.

A society composed of so large a number of gentlemen, being members of a profession who, as a body, stand equal to any in the world, for education, science, intellectual refinement, and christian charity, ought to make those qualities conspicuous in all their undertakings, and not confine them simply to the exercise of the duties of their profession, but with equal kindly bearing, charity, liberality, and benevolence towards each other.

If you think the rules and regulations for the establishment and management of the “*Supplemental Fund*” of the Medical Officers of the Navy would be of any use to you, I shall be happy in sending them, together with Swedish tables.

Hoping you will not let the next general meeting of the Association pass without previously preparing the members for the consideration of this important subject, and laying some effective plan before the body so assembled suitable for the attainment of the desirable objects now in question,

I remain, my dear Sir,

Yours very truly,

JAMES HOLBROOK.

ON THE INFLUENCE OF THE MOTHER ON THE FŒTUS.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND
SURGICAL JOURNAL.

SIR,

The communication of a paper in your Journal of March 7th, from Dr. Butler Lane, respecting the supposed influence of the mind of the mother on the fœtus, has brought to my recollection a curious fact which occurred under my observation. Some years since I was required, in the performance of my duty as Medical Superintendent of Quarantine at this port, to visit one of the “*packets*,” on her return from a Brazil voyage. On mustering the crew, I found one absent, and on inquiring the cause, I was informed that the man had sustained a severe injury of the spine from falling down the hatchway, was paralyzed in both arms and legs, and could not be brought on deck without much trouble.

A communication was quickly made by some good-natured friend to the wife of this poor fellow, who was then in the fifth month of her pregnancy, that he was killed; but somewhat of a more correct account was shortly after brought her, that her husband was not killed, but had *lost both arms and legs*.

The woman at the proper time gave birth to a fine male infant, without *legs or arms*; in every other respect well formed. The child lived about two years, was exhibited as a show, and was a remarkably handsome boy. The shoulders were beautifully rounded without the vestige of a humerus, but from one groin there was protruded a great toe, and from the other groin two of the smaller toes, in all of which the child had perfect flexion.

It is fair to state, that the mother herself did not refer the cause of the child's dismemberment to the shock she experienced of hearing of her husband's accident, but to having been previously frightened at seeing a turtle! The coincidences are in every way curious, and deserving of investigation.

I have the honour to be, Sir,

Your obedient servant,

JAMES CORNISH.

Falmouth, April 23, 1849.

Medical Intelligence.

PRESENTATION OF A TESTIMONIAL TO DR. FORBES.

The Committee appointed at the general meeting by the subscribers to the Forbes Testimonial, to expend the sum collected, in the purchase of a piece of plate, presented this Testimonial to Dr. Forbes on the evening of the 3rd of May. The Committee invited the subscribers in London and its vicinity to meet them on the occasion, and nearly one hundred professional gentlemen obeyed the summons. The Testimonial consists of a very handsome piece of plate, a candelabrum and epergne, beautifully designed and executed by Messrs. Smith, of Duke Street, Lincoln's Inn Fields. The stem is supported by three figures, representing Industry, Health, and Hope, corresponding to Dr. Forbes' motto, "*labore robore spe.*"

Mr. Stanley, President of the Royal College of Surgeons, presented the Testimonial to Dr. Forbes. After a short allusion to the circumstances in which the subscription originated, Mr. Stanley proceeded to read the following address, framed by the Committee in accordance with the resolution passed at the general meeting:—

Sir,—“On the occasion of your relinquishing the editorship of the *British and Foreign Medical Review*, it was felt by many of your friends and the admirers of that journal, that a proper opportunity had arrived for expressing to you their sense of the deep service you had rendered to medical science, by the spirit and method in which, for twelve years, you conducted that important and influential publication. It would be out of place to enter here into any statement of the mode in which that journal was conducted, or into any estimate of the great influence it from the first excited on English medical literature,—an influence, we may add, which still continues, and which is not likely soon to pass away. Suffice it to say, that you brought to the task of editorship intellectual and moral qualities of so high an order, that your Review was at once placed in the foremost rank among the journals of periodical criticism, both medical and general. It was impossible that such a journal should cease to appear without some acknowledgment on the part of those who had so largely benefitted by it. It would have been an act of injustice if no record of regret had been entered to mark the close of its useful and honourable career. A subscription was therefore opened, to present you with a Testimonial, in expression of the sense of your professional brethren on the occasion; and the rapidity with which the lists were filled, testifies to the esteem with which you are universally regarded.

“We may be permitted also to add that we do not present this Testimonial only to the late editor of the *British and Foreign Medical Review*, but also to the man whose excellent moral character is no less remarkable than his wisdom and sagacity; to the physician who has played an important part, and filled many important positions, without ever forgetting that life

is a sacred trust, which we are bound to keep pure and unsullied; to the physician who is, if any one is, a pattern to the younger members of our profession, of truthfulness, manliness, and sincerity.

“We will not occupy your time further than to give expression to the earnest prayer of this assembly, that many years may be permitted to you to enjoy the honour which your professional brethren now offer you.”

Mr. Stanley then said—In the sentiments expressed in this Address, Dr. Forbes, I most heartily concur, and I am happy that it has fallen to my lot to discharge the pleasing duty of presenting it to you. It is a most gratifying circumstance to me individually to find that the merits of one whom I esteem so highly have drawn forth this public expression of gratitude and regard; and, on public grounds, I cannot but rejoice that the services which have been so well and so manfully rendered have met with spontaneous and immediate recognition.

Dr. Forbes replied—I have, Sir, on many occasions regretted that I did not possess the happy art of giving appropriate words to feelings which demanded utterance, and never have I regretted it more than on this occasion. But I console myself with the thought that it is not for making speeches, for throwing easily vivid thoughts into eloquent words, that so many of the most eminent of my professional brethren have assembled here this evening to confer on me this great honour, but for a strenuous endeavour to discharge a duty which I had assumed, and to fulfil the tacit guarantee into which I entered when I became the editor of a journal of periodical criticism. And on this ground I do not refuse the honour you offer me; I do not deny that when I established the *British and Foreign Medical Review* (although I did not altogether exclude personal and private considerations) I did so mainly on public grounds, because I thought such a journal was wanted, and would do good service to the profession. But, Sir, I cannot permit myself to assume all the merit you have attributed to me in the too flattering address you have now read. The merit of the journal which I lately conducted, of its literary pretensions, and of its philosophical acumen, is not due to me, but to the band of admirable contributors whom I was enabled to assemble round me. In their names I will not refuse the terms in which you have been pleased to speak of that journal. I may have appeared as an occasional contributor, and more frequently as the reviser or corrector of the criticisms of others, but the chief part of my duty was to see that the works of authors went into competent and impartial hands, and were criticised by men who, as far as I could judge, were the most likely to give a true and unbiassed account of their contents. And, Sir, I believe that, as far as is possible, the criticisms in the *British and Foreign Medical Review* were able, were honest, were unstained by feelings of petty rivalry, and untarnished by the bias of personal enmity. It was at least my intention to make them not only sound in philosophy, but also just as to the author's merits. That my endeavour was, at any rate, partially successful, I have the high gratification of feeling

this evening, Sir. That magnificent piece of plate, valuable as a mere mass of metal, valuable as a work of art, has yet to me a value of a different kind, which is not to be measured by gold, nor supported by the most perfect of human productions. The editorship of the *British and Foreign Medical Review* was to me no ungrateful task: it was not performed with pain and repining; on the contrary, it was a pleasure to me, a gratification of all my faculties, a true labour of love. But had it been otherwise,—had it been, indeed, a hard task performed with sighs, and urged by painful necessity,—I should have been repaid for it now. Now I should have received my reward, and have taken the vantage ground from fortune. For a man may be justly proud when he finds his labours thus rewarded, by the approbation of many of the most eminent of the profession, not only in this country, but also in America—that mighty state which is indissolubly connected with Great Britain by so many ties of common interest. That Testimonial, Sir, shall be to me the dearest of my possessions: whatever may happen to me, from it I will not be separated; and it shall be cherished by my children when I can receive no more pleasure from it.

I feel, gentlemen, that I have most imperfectly expressed my grateful feelings towards you. You will understand what it is not easy to put into words. Permit me, Sir, to acknowledge the kind terms in which you individually have spoken of me, and which, from you, are words indeed of worth.

Dr. Forbes was loudly applauded by the audience, and shortly after the conclusion of his speech, the meeting separated.—*Medical Gazette*.

BENEVOLENT FUND.

As the accounts of this fund are rigorously closed on the 30th of June in each year, and as there still remain a few subscribers in arrear of their present year's subscriptions, an *immediate remittance* of the same is most earnestly solicited.

Gentlemen who would kindly be willing to undertake the office of Local Secretaries, in their respective districts, are requested to communicate their names to

WILLIAM NEWNHAM, Esq.,

Treasurer and Hon. Sec.

Farnham, May 29, 1849.

APPOINTMENTS.

Mr. John Birkett was appointed Assistant-Surgeon to Guy's Hospital, on the 23rd instant.

M. Bérard has been appointed a member of the Committee for the Inspection of Hospitals in Paris.

ROYAL COLLEGE OF SURGEONS.

Gentlemen admitted Members, Friday, May 18th:—Messrs. W. Henderson; N. S. Wood; S. Whitlow; S. Partridge; C. A. Poole; R. Creighton; H. D. Smith; T. T. Frankland; T. C. Marrett; F. J. Gant; T. L. Ridley; G. Wilson.

OBITUARY.

Died, May 18th, aged 30, of fever, W. L. Grundy, Esq., one of the Poor-law Medical Officers of the Wolverhampton Union.

PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION.

NOTICE TO MEMBERS.

Gentlemen who have not yet paid their subscription for the current year, or who are in arrears, are requested immediately to forward the amount due to the Secretary or Treasurer of the Association, as the accounts are now about to be made up for the Annual Meeting.

* * As the list of Members is about to be published in the next Volume of the "Transactions," gentlemen whose addresses are not correctly stated in the last volume, are requested to forward the alteration immediately to the publishers, Deighton and Co., Worcester.

J. P. SHEPPARD,

Secretary to the Association *pro tem*.

TAUNTON AND SOMERSET BRANCH MEETING.

The Annual Meeting of the Members of this Branch will be held at Pattison's Castle Hotel, Taunton, on Wednesday, the 13th day of June next. G. Brock, M.D., President; H. Alford, Esq., F.R.C.S.E., President-elect. The Chair will be taken at 2, p.m.

FRANCIS HENRY WOODFORDE, M.D.,

Honorary Secretary.

Taunton, May 26, 1849.

SUFFOLK BRANCH MEETING.

The Anniversary Meeting of the above branch of the Association will be held at Hadleigh, on Friday, the 15th of June.

Members of Council will meet at the residence of the President Elect, John Growse, Esq., at one o'clock, and the chair will be taken at the general meeting, at two o'clock precisely.

Those members who cannot attend will oblige me by forwarding any communication they may wish to be brought before the meeting. Short papers or interesting cases will be acceptable. Dinner at five o'clock.

The contiguity of Hadleigh to the county of Essex will, we trust, be taken advantage of by members of the Association, or their friends, residing in that county.

C. R. BREE, Hon. Sec.

TO CORRESPONDENTS.

Communications have been received from Dr. Toogood; Dr. Copeman; and Dr. Norris.

In consequence of the lamented death of Dr. Streeten, it is requested that all letters and communications be sent to J. H. Walsh, Esq., Foregate Street, Worcester. Parcels and books for review may be addressed to the care of Mr. Churchill, Princes Street, Soho.

PROVINCIAL MEDICAL & SURGICAL JOURNAL.

A COURSE OF LECTURES ON SURGERY,

DELIVERED IN THE

MEDICAL SCHOOL OF CAMBRIDGE.

By GEORGE MURRAY HUMPHRY, Esq., Downing
College, Surgeon to Addenbrooke's Hospital.

LECTURE IX.

ULCERATION CONTINUED: MORTIFICATION.

Phagedenic Ulcers, their General Characters; are often of Specific Nature; Cause of the Ring or Crescent Shape; Treatment by Caustic; Specific Remedies; Tonics and Opium.—Atonic Ulcers, their General Characters; Circumstances under which they occur; Treatment.—Mortification, its relation to Ulceration; the two often conjoined; Classification of the cases of Mortification into Inflammatory, Phagedenic, and Atonic.—Inflammatory Mortification: Symptoms, Local and General; Resistance of Different Tissues; Treatment.—Sloughing Phagedena; Symptoms and Treatment.

The acute and chronic inflammatory ulcers which I described to you in the last lecture constitute the great proportion of this class of diseases; they are, for the most part, simple in their nature, and the indications for their treatment are generally obvious. Though often very tedious and troublesome, they scarcely deserve to be regarded as difficult cases. I gave the name *inflammatory* to them, because they evince, in the rate of their progress, a greater correspondence with the severity of the accompanying inflammation than do the ulcers we are now about to consider, and the treatment of them consists in the employment of the various means which are used to combat inflammation in its acute and chronic stages.

In the second class of ulcers to which I would now direct your attention, the correspondence between cause and effect,—between the inflammation and the ulceration, is not so manifest. The latter is observed to be out of proportion to the former. The distinguishing character of these ulcers is their tendency to increase without being accompanied by any sufficient apparent cause for so doing. They go on spreading from point to point, as if they possessed an independent power of growth, and as they proceed, they eat away the integuments and subjacent parts, which may look quite healthy, and may present scarce any trace of

inflammation up to the very edge of the ulcer. I do not mean to say that these ulcers really take place without inflammation, or that the destructive process is less directly dependent on inflammation in them than in other ulcers, but merely that the ulceration is so greatly out of proportion to the inflammation, that the latter seems rather a secondary feature than an exciting cause. The term *phagedenic*, which is applied to these ulcers, is expressive of this eating or destructive tendency so strongly marked in them. They are very often the result of some specific disease, as syphilis, the influence of which seems, to a certain extent, to modify the ordinary course of the inflammation, and to impress peculiar characters upon the ulcer.

Phagedenic ulcers are generally of circular or crescentic shape, and they sometimes exhibit a remarkable tendency to spread in one direction, while they are healing in another. Thus the reparative processes of granulation and cicatrization are often observed to be going on from some remaining insular fragments of cutis, which have escaped destruction in the middle of the ulcer, at the same time that the work of destruction is proceeding at the circumference; and when the ulcer is of crescentic shape, cicatrization is generally advancing on the convexity, while the ulceration continues to make way in the concavity of the crescent. The destructive and reparative processes thus going on together, and keeping pace with one another have the effect of gradually enlarging the circle of disease—it may be, without increasing the interval between the ulcerating and the healing lines. Moreover, these ulcers are generally superficial, creeping along the skin without extending through the subcutaneous tissues; and, although they continue to spread at their circumference, the abundant granulations on their surfaces, forming, perhaps, at the same time, show the reproductive forces to be in full vigour at one part, while the work of destruction is going on at another.

This disposition to assume a circular or crescentic shape, and to heal at the centre, while they spread at the circumference, though often strongly marked in syphilitic ulcers, and forming, therefore, a suspicious symptom, is not altogether peculiar to them. The circular is the natural shape assumed by inflammatory affections of all kinds, which commence at a single point, and radiate from it. It is liable to be modified by the unequal resistance of the tissues to the spreading of the inflammation, and by various accidental circumstances, and is generally best marked when the disease

increases slowly. The central healing and circumferential spreading of an inflammation upon which the crescent or ring-shape depends, has its analogy in the fairy rings upon grass, and is observed in other inflammatory affections besides syphilis. It is no uncommon occurrence in scrofulous ulcers, and is the cause of that disease being very often confounded with syphilis. Herpes circinatus, or ring-worm, and lepra (common, not syphilitic lepra, for I believe the spots of the latter do not attain sufficient size to assume the ring-shape,) are familiar examples of the same thing. The peculiar shape and mode of increase in these cases probably depend upon the tendency which inflammation, in common with other diseases, have to run their course, and fade away, on the one hand, and to communicate their noxious influence to neighbouring parts on the other. Thus an inflammation attacking a given point in the skin, runs its course in due time, and subsides at that point; but it has, in the meantime, infected the surrounding integuments, proceeds through the same course in them, and is from them propagated to a greater distance. In this manner a spreading circumference is established around a healing centre. Such mode of increase is most likely to be observed in specific affections, because the disease, depending upon a poison or some extraneous cause, falls upon structures otherwise healthy, and has an opportunity of exhibiting its natural disposition, uninfluenced by the many causes which, under ordinary circumstances, combine to modify it. If this view of the subject be correct, the peculiar shape of phagedenic ulcers is due to the natural unrestrained tendencies of the ulcerative process, rather than to the exercise of a specific influence.

Inflammatory affections are observed to assume the ring or crescent shape chiefly when they depend upon some morbid condition of the circulating fluids, or upon some depraved state of the constitution, doubtless, because they are then least likely to be modified by local influences. Lepra, herpes, some of the forms of roseola, and erythema, and occasionally scrofulous inflammation, are instances of this, and it is probable that the shape of the secondary syphilitic ulcer has a relation to the mode in which the poison of syphilis is propagated through the blood, rather than to the quality of the poison itself. This inference seems to be justified by a comparison of the syphilitic ulcers with the diseases just referred to, for they all agree with one another, and with the secondary ulcers of syphilis, in a disposition to assume the ring or crescent shape, and they all appear to depend upon some morbid condition of the blood, with the exception of scrofulous inflammation, which probably owes its peculiarities to a particular state of the constitution. The primary syphilitic sore, though of specific nature, as shown by its effects, is a local disease dependent on a local cause, and displays nothing remarkable in its shape.

It generally happens in an ordinary ulcer, that the integuments have been quite destroyed in the middle of the sore, so that although granulations may rise up in the centre while ulceration is going on at the margin, cicatrization can proceed only from the circumference; whereas, in the secondary syphilitic ulcer, which com-

mences often with a cluster of minute points, small fragments or islands of incompletely destroyed cutis remain in the middle, and become nuclei, from which the cicatrization may radiate, and this central healing taking place co-temporaneously with the circumferential spreading, gives the peculiar shape we have been discussing.

Phagedenic ulcers are often very painful, the pain being of a sharp gnawing kind. It is severe in proportion to the rapid spreading of the ulcer, and ceases as soon as the process of destruction is brought to an end.

In the first class of ulcers which I described to you, inflammation is the leading feature, and the treatment is regulated accordingly; but in the phagedenic cases, where ulceration is so predominant as in a manner to constitute the disease, we do not proceed by the circuitous course of endeavouring to control the inflammation, but at once attack the disease in some more direct manner. With this view, caustics are applied, and often successfully, to phagedenic ulcers. The disease is by this means literally burnt out. The ulcerating structures are converted into a slough, which separates in the usual manner, and the healing processes succeed. A primary syphilitic sore may be thus exterminated if the treatment be adopted before it has become indurated, and before it has had time to infect the system. The nitrate of silver is not generally sufficient to effect this; it rather increases the spreading than effects the eradication of the sore. Some stronger caustic, such as nitric acid, or potassa fusa, must be employed. The spreading of larger phagedenic ulcers not of primary syphilitic nature, may be sometimes stopped by touching their edges lightly with nitric acid; and you have had repeated opportunities of witnessing the good effects of applying nitrate of silver, in substance or strong solution, to acute ulcers of the cornea, which are not attended by a sufficient amount of conjunctival inflammation to correspond with the severity of the disease.

The exhibition of mercury in sufficient quantity to affect the system, generally succeeds in stopping the primary phagedenic ulcers which have advanced too far for the application of caustic. The same remedy is much less beneficial when the phagedenic ulceration occurs in the subsequent stages of syphilis; indeed, it is then rather injurious. The iodide of potassium is in such cases no less a specific remedy for the syphilitic disease than the mercury is found to be in its primary stages. I believe that both these medicines in course of time lose their influence, and if the disease outlives that period, it is exceedingly difficult to control.

Phagedenic ulceration occurs most frequently, and advances with greatest rapidity in persons of feeble or debilitated constitution, the reduced vital powers of whose tissues are unable to resist the destructive progress of the disease. Patients who are suffering under what is called the tertiary stage of syphilis, in which phagedenic ulceration of the skin and fauces constitutes a prominent feature, are often in a very low state of health. I believe that the long continuance of the syphilitic poison in the system exerts a directly enervating influence upon the bodily powers, which has

much influence in reducing the patient to the cachectic condition so often attendant upon the later, and sometimes even accompanying the earlier stages of the disease; and if the specific remedy for the syphilis have not lost its effect, it will be found, in such cases, the very best means of combating the cachexia. I have often known patients loaded and oppressed apparently with the poison of syphilis, improve greatly in health, and resume their lost vigour as the disease faded away under a carefully conducted mercurial course. In this tertiary stage of syphilis, however, when debility is associated with phagedena, a tonic regimen, nutritious diet, sea-side air, and tonic medicines, such as sarsaparilla, nitric acid, and cinchona, are powerful adjuncts to the specific remedy, and, when the latter has lost its influence, we are obliged to rely exclusively upon these measures for invigorating the system, so as to enable it to withstand or throw off the noxious poison.

When the patient is anxious, irritable, and sleepless, and the spreading ulcer is painful, much benefit is likely to attend the administration of opium. It should be given in sufficient quantity to ensure sleep at night, and it is sometimes advisable to give it in repeated doses during the day. It sometimes acts like a charm, and, in combination with tonic medicines, has acquired the reputation of a specific in some of these cases.

In our third class of ulcers,—the *atonic*, ulceration is out of proportion to the accompanying inflammation in consequence of the enfeebled condition of the patient, the vital powers being reduced to so low an ebb that the tissues are unable to maintain their integrity, under circumstances which, in the healthy state, would have failed to produce a destructive impression upon them. One person receives a wound, and it heals up readily and quickly; but in another, and more feeble patient, the surrounding textures being unable to bear the slight disturbing influence of the inflammatory action which accompanies the healing process, give way and ulcerate, and the wound, instead of closing, becomes larger. Hence, the troublesome ulcers caused by wounds in the extremities of old people, in anasarous limbs, and in persons greatly reduced by illness or starvation. This disposition to ulcerate rather than to heal is no uncommon cause of death after the amputation of diseased joints and limbs, when the patient's strength has been greatly reduced before the operation is performed. It may be that the stump never heals at all, the slight inflammatory disturbance necessary for reparation, producing a destructive effect upon the enfeebled tissues from the very first. Or, supposing the healing process to have commenced, if any slight accident, such as the loss of a small quantity of blood, a diarrhoea, or disordered state of stomach occur, which lowers the patient's strength a little further, the bond of union is very likely to give way, and ulceration takes the place of reparation. A patient in this hospital underwent amputation in the thigh on account of a severe disease in the knee joint, with extensive suppuration, which had reduced his strength very much. The operation was performed with little loss of blood, and abundance of soft parts

were left to cover the bone; but the stump healed only in part; abscesses formed in it, and after a time, the bone projected through the wound. Such tonic medicine and nutritious diet was given as his stomach was able to bear, but he never made a fair start on the road to health; the quick pulse, hectic sweats, and an open stump remained. After he had lingered in this way for a considerable length of time, inflammation occurred in the opposite femoral vein. This was followed by the appearance of an ulcer on the inside of the stump taking place without any apparent local cause. The ulcer spread rapidly, so that in ten days it was as large as a cheese plate. Its surface was grey or ashcoloured, and sloughy, and there was very little inflammation in the skin immediately surrounding it. It was a well-marked specimen of an atonic ulcer, and I need scarcely add that the patient soon died.

Some of you may remember a pale, haggard, emaciated woman, aged 54, with diarrhoea, small quick pulse, parched lips, and glazed apthous tongue, who was admitted into Anne's Ward several months ago, with extensive ulcers, of the atonic kind, on the left lower extremity below the knee. They were covered by soft grey sloughs, and in places where these sloughs had separated, the muscular fibres were exposed, uncovered by granulations. A copious creamy offensive discharge issued from the ulcers. The surrounding integuments were pale, not much inflamed, and when slight inflammation occurred in the course of the femoral absorbent vessels, it was very quickly followed by the formation of abscesses and ulcers, similar to those in the leg. She had long been subject to ulcers in this leg, but the deplorable condition in which she was admitted into the hospital, appeared to have commenced three or four months previously, with loss of appetite, and general failure of strength, after which the ulcers in the legs began to spread rapidly. Stimulants and nutritious diet failed to impart any vigour to her shattered frame, and she died soon after her admission. The internal organs were sound, but bloodless.

These atonic ulcers occasionally present the character which I have mentioned as appertaining to the phagedenic class. There is at this time in Martha's Ward a pale, feeble, emaciated woman, whose lower extremities are the seat of ulcers, of a peculiar kind. In the early stage they were covered by thick yellowish secretion, forming a crust or scale upon them. They were all superficial; several of them had an ulcerating edge in one direction, although they were healing at other parts, and although their surfaces were covered by large flabby granulations. Some were healing at the centre, and spreading at the circumference, and others were of crescentic shape, with cicatrization at the convexity, and ulceration at the concavity of the crescent, simultaneously proceeding. There were also at the time of her admission superficial ulcers of the scalp over the coronal suture, and some symptoms of disease of the frontal bone. Though the appearances of the ulcers were very suspicious, we could not obtain any history of syphilitic disease, indeed the evidence is strongly against it. She is a respectable married woman, with five children, the youngest of which, a

year old, had been weaned three months. She states that at the time of weaning this child her breast became sore, this was followed by an abscess in the axilla, which made her very weak. The ulcers upon the head and lower extremities began soon after, and have been on the increase ever since. At first, under nutritious diet, with small doses of the iodide of potassium in decoction of sarsaparilla, the healing of the ulcers went on very favourably, though the cicatrices were thin and delicate, without contractile power. Lately, however, her health has declined again, the ulcers have, in many places, re-opened, and she is in a worse condition than before. I cannot, of course, be quite certain of the absence of a syphilitic taint in this case, but I think the probabilities are against there having been any disease of that kind; and I have before mentioned to you that the ring or circular shape is not a certain evidence of the specific nature of an ulcer. However, whether the disease in this case be syphilitic or not, it is an instance of the association of phagedenic ulcers, with a cachectic state of the system, which I before mentioned to be of frequent occurrence.

The aphthous sores frequently affecting the mucous membranes of persons who are greatly exhausted by long-continued disease, are also examples of the atonic class of ulcers. So are the ulcers sometimes occurring upon the feet and legs of old people, the ulcers of scurvy, and ulcers affecting limbs weakened by paralysis or other disease.

In the treatment of this class of ulcers our attention is directed to the means best calculated to promote the general health; but, as in the cases which I have related to you, the condition of the patient is generally so miserable and cachectic, that our best efforts are unavailing.

These three classes which I have now described, (the inflammatory, the phagedenic, and the atonic,) will, I think, be found to include all the various ulcers, with the exception of such as depend upon a peculiar cause,—for instance, syphilis, malignant disease, or a scrofulous habit of body.

By the term mortification, we mean the death of a part of the body which is generally preceded and occasioned by some change in the vital actions of the part, wherein it differs from simple death, or death consequent on amputation, or the decease of the entire body. It is indicated by loss of temperature and change of colour. The limb affected becomes cold, and of a mottled, livid, or black colour, the cuticle being at the same time vesicated in places, or detached. When the change is confined to some of the textures only, they more frequently assume a grey or ash colour, and become soft or sodden, as if from the infiltration of fluid into them. The terms *spacelus*, *gangrene*, and *sloughing*, are applied almost indiscriminately to this condition, at any rate the distinctions between them are not very accurately observed.

Ulceration and mortification differ from one another in degree rather than in kind. In the one the death of a part takes place slowly, *piecemeal*, or by atoms; the other is more rapid in its progress, does its work of destruction upon larger masses at one time, entire structures, or even a whole limb, dying at once, *en*

masse. Both are also the result of the disturbing agency of inflammation upon the tissues. They are, therefore, alike in their nature, and dependent upon the same cause, and we should expect to find them treading closely upon each other, the one continually advancing into the other, and both proceeding together in the same part; and so it is, for we very seldom see ulceration going on with any great activity without its being accompanied by mortification of the affected tissues, to a greater or less extent. The ulcers in which mortification is thus combined with ulceration, are called "sloughing ulcers." Their only peculiarity consists in the rapidity with which the work of destruction is carried on, and the treatment of them is to be conducted upon the general principles which I described to you in speaking of the treatment of ulcers. If a poultice be placed upon the part, (and it is generally the most desirable, as well as the most comfortable application,) some detergent or cleansing preparation may with advantage be added to it, such as chloride of lime or charcoal, which, by destroying the noisome products of the disease, exerts some influence in arresting the disease itself.

Sloughing is most likely to occur in the ulcers which are attended and occasioned by acute inflammation, and in the atonic ulcers. The latter class of ulcers, indeed, very often seem to spread rather by sloughing than by ulceration. It is also to be remarked that the textures of low vital power are more liable to mortification than to ulceration. This is true of fibrous textures and of bone; so that when an ulcer has penetrated through the skin and subcutaneous tissues down to a fascia or tendon, those structures generally mortify and are separated as soft, sodden, greyish masses. Inflammation of a bone, especially if it be at all acute, is more commonly followed by necrosis than by ulceration, and ulcers in bones are generally attended with more or less of necrosis. Again, ulcers in cicatrices and in textures indurated and otherwise altered and weakened by previous inflammation, advance rather by sloughing than by ulceration. An injury which would occasion a slight ulcer in a young or middle-aged person, may cause severe mortification in the foot of an old man. All this agrees with the statement I have before made to you, that the destructive effects of inflammation are most marked and most rapid in persons and tissues possessed of the lowest vital powers.

Moreover, as on the one hand, mortification is the usual attendant on the more severe stages of ulceration, so, on the other, does ulceration generally accompany the milder forms of mortification; and when the latter has ceased to proceed ulceration continues to finish the work which it had begun. In this manner ulceration exerts a benign influence. By separating the dead parts it clears away the foul products of mortification, and leaves a clean surface on which reparation may proceed.

The several instances in which mortification occurs may be advantageously classed in three divisions, corresponding to those into which we separated the different kinds of ulcers. The first class comprises the cases in which the mortification manifestly depends

upon, and is proportionate to, the attendant inflammation. In the second class we will consider those cases, not of very frequent occurrence, where the mortification is disproportionate to the inflammation, and seems to spread in consequence of some peculiar quality in the disease; and, thirdly, the more numerous instances in which the mortification, in its severity, exceeds the severity of the accompanying inflammation, by reason of the low vital powers of the person or part affected. We have, therefore, simple or inflammatory, phagedenic and atonic mortification.

In the first class of cases the inflammatory process attains to such a degree of violence that it not only renders the nutritive fluids unfit for their purpose and stops the process of nutrition, but it also annihilates the vital properties of the part affected and reduces it to a lifeless mass. Function of every kind, nutrition, and secretion are suspended, and the tissues become subject to the decomposing tendencies of compound structures; or they may be dried and charred to a cinder. The first symptoms which attract our attention when inflammation is about to pass into mortification are a change of colour and a loss of temperature. The bright red colour and burning heat of acute inflammation are succeeded by a dull red, blue, or livid hue, indicating the languor and difficulty of the capillary circulation. At the same time the part begins to feel cold, relaxed and flabby; and it is generally infiltrated with thin reddish fluid. The acute sense of pain, perhaps, begins to subside, so that judging from the pain which may have been a prominent symptom, and to the patient the most important one, the attendants are likely to be misled into the idea that the inflammation is giving way, and that an improvement has commenced. (This is particularly likely to happen when the inflammation attacks an internal organ, the indirect symptoms resulting from it being then the only means by which we can form an estimate of the changes that may be in progress.) As the mortification advances the cuticle becomes detached, vesication perhaps takes place, and the part assumes a mottled colour, then becomes dark, blue, leaden, brownish or even black; it is cold and flaccid, a dirty, thin, bloody fluid exudes from it, and sensation is quite destroyed. Decomposition quickly following, gases are generated, occasioning a crepitating feel and a fætid odour; the textures become stained of an uniform dull livid hue from the transudation of the colouring matter of the blood, and they are rendered soft and sodden so that they tear like wetted paper.

While the inflammation is thus at one place advancing to the complete destruction of the textures, the surrounding parts may exhibit the several changes above described proceeding at different points. The brownish black colour of the dead and decomposing structures may be shaded off at the circumference into a livid, blueish or mottled appearance, and this again may pass in the same manner by easy transition into the bright red colour, and the burning heat of acute inflammation still raging in the most distant parts. So that there is no abrupt line of demarcation between the inflammation and the mortification; the one is by imperceptible degrees advancing into the other. While

this is the case we know that the mortification is extending and we cannot tell where it may stop. As soon, however, as the destructive process is arrested, either in consequence of a diminution of the intensity of the inflammation, or from the greater vitality of the textures involved in it, then the intermediate livid shades begin to disappear, and a well defined line appears between the living and dead parts. The contrast between the two is very remarkable, because the black slough is surrounded by the inflamed integuments whose bright red colour extending to the very edge of the slough shews that they have not yet begun to lose their vitality.

The mortified part may now be regarded as a foreign body, which by its presence maintains a sufficient degree of inflammation in its circumference to effect the removal by ulceration of the tissues in immediate contact with it. So that in the line of demarcation between the dead and living parts, a narrow groove of ulceration takes place, and extends more and more deeply till it has completely detached the mortified part. This ulceration occurs, of course, in the living textures contiguous to the slough; for the dead structures cannot undergo changes which are the result of a modification of the vital powers. The time required for the complete separation of the slough varies a good deal; in vascular and highly organized textures, as the skin and mucous membranes, it is quickly effected. The slough of a caustic issue comes away in a few days. When the mortification has attacked a limb, and the ulceration has to make its way through all the structures before the slough can be separated, it is a work of some months; for the fasciæ, tendons and bones are, as you know, very resistant to the ulcerative process.

When the slough has separated, the ulcer granulates and heals up like any other sore; and it often does so very quickly, because the inflammation which occasioned the mortification having been active in its progress, has left little induration or other traces of its injurious effects upon the surrounding parts. There is, therefore, nothing to impede the contraction of the ulcer, and the work of reparation generally goes on briskly also.

The effect produced upon the constitution by the transition of inflammation into mortification is very marked, and is proportionate to the extent of the disease, and the importance of the part affected. The change in the constitutional symptoms corresponds closely with that of the local phenomena. A state of great depression follows upon that of much excitement. There is general listlessness and prostration of strength; the countenance becomes sunken, leaden, and cadaverous; the surface of the body cold, flaccid, and clammy with perspiration; the pulse quick, feeble, hesitating, or intermitting; the tongue moist, flabby, and cold; the secretions, with the exception of the perspiration and a few others, stopping, and the intellect wandering. These symptoms of depression are the worst that can occur in the course of an inflammatory affection, for they indicate, either that the local disease has gone on to its most destructive results, or that it has attacked an organ of such importance

that the constitution is unable to bear the sympathetic disturbance excited by it. It does not necessarily follow that mortification has commenced, for we find the symptoms of depression sometimes accompanying even the early stages of inflammation of a vital organ, or of the peritoneum. They are more easily induced by the inflammatory affections of old people than in the young and vigorous; but under any circumstances they are alarming symptoms, for, whether the local disease be severe or not, they shew, at any rate, that the constitution is ill able to bear it. And when the inflammation is seated in an internal organ, and so out of sight, they demand our serious attention, because they may be the only warnings that reach us of the terrible mischief which is going on within.

The mortification consequent on acute inflammation is not often very extensive, unless there be some peculiar circumstances connected with it. It commonly affects tissues rather than limbs, and, as I have before mentioned, it affects most easily those tissues whose vital powers are the least active; thus, in cases of severe inflammation of the fingers, the tendons and the phalanges are the parts whose vitality is first destroyed. The cellular tissue is very prone to mortification, and so is the skin in a less degree. When the mortification is limited in its extent, the sloughing tissues generally present a grey or ash-colour, instead of being livid or black.

Blood-vessels resist mortification a very long time, and may be sometimes found unchanged when the surrounding tissues are sloughing extensively. When they begin to suffer, the blood usually coagulates in them, and the coagulation may extend for a considerable distance above the mortified part, so as to plug up the tube, and prevent any loss of blood when the slough is separated by the ulcerative process. This coagulation does not always take place in mortifying vessels. Thus, in cases of acute gangrene of a limb, the blood is generally found to be fluid, and the tissues are stained by the transudation of its colouring matter. It seems that the blood and tissues all perish together when the mortification is thus rapid, there being no time for the coagulation of the blood to take place; just as in sudden death from electricity or any other severe shock, which is felt throughout the whole frame, at once annihilating life in every part, in the fluids as well as in the solids, the blood in the heart and great vessels, and indeed, elsewhere, remains in a fluid state.

The most effectual means of preventing the progress of acute inflammation into mortification, are those which serve best to control inflammation under other circumstances. If the fever be high and the pulse hard, general depletion is required, and the antiphlogistic regimen should be enforced, warm soothing applications to the part generally answer better than cold lotions, indeed, the latter sometimes seem to accelerate the mortification. Leeches should not be applied upon or in the immediate neighbourhood of the inflamed part.

Even when the mortification has actually commenced, if it affect only a small part of the body, and the febrile symptoms continue, the loss of blood, and the antiphlogistic regimen, may still be necessary. In

adopting these measures, you must exercise much caution, and not forget the severe constitutional depression which is likely to be induced when mortification has once set in. I need not say that when the depressing influence has begun to extend from the mortifying part to the system, and the symptoms of sinking which I just described have commenced, such treatment is quite out of the question. Our efforts must then be directed to support the drooping frame by stimulants, and to allay the local pain and the nervous irritability by sedatives; brandy and laudanum, or ammonia, with cinchona, beef-tea, &c., must be given, if the stomach do not reject them, and warm fomentations be applied to the part, together, perhaps, with chloride of lime, charcoal, or other purifying agents.

The exhibition of tonics and nutritious diet is not often attended with much benefit till the mortification has ceased to spread, and the ulcerative line of separation has commenced; their good effects is then very apparent, more particularly if the separation of the slough, the granulation, and cicatrization, proceed languidly. The activity of these processes may be also sometimes increased by mild stimulating local applications, such as yeast poultices, weak solutions of sulphate of zinc, or a diluted preparation of nitric acid. It is sometimes desirable to expedite the removal of the dead and stinking mass, by dividing the tendons, bones, or other parts, in which the process of ulceration goes on slowly. This should be done carefully, so as to avoid injuring the adjacent lining structures.

Our second class of cases of mortification consists of the instances in which the progress of the disease corresponds with that of the phagedenic ulcers, the destructive results being disproportionate to the inflammatory symptoms, without there being any peculiarity of constitution sufficient to account for the rapidity and extent of the mortification. We can explain such cases only on the supposition of there being something peculiar in the nature of the disease, which makes it differ in its effects upon the tissues from ordinary inflammatory affections. That peculiarity, as in the phagedenic ulcers, is often due to a specific cause. Thus syphilitic ulcers not unfrequently spread by sloughing. The affection called sloughing phagedena is a better instance of this second class of cases of mortification. It consists in a rapidly-spreading slough, observed most frequently about the pudenda or nates of prostitutes who are suffering under gonorrhœa or some form of syphilis. It commences with an ulcer or abrasion of the skin, which is quickly followed by sloughing; the slough extends without much accompanying inflammation. It invades and destroys the surrounding textures, converting them into a dark or ash-coloured toughish mass. This affection is observed in persons who are out of health, and who have been leading the debauched irregular lives of prostitutes; but the constitutional derangement is not sufficient to account for the rapid progress of the local disease which seems to spread by some force of its own. The most effectual treatment consists in killing as it were the local disease, by applying strong nitric acid freely, so that it may soak through the slough, and exert its

influence upon the surrounding tissues. The eschar made by the nitric acid comes away with the slough, and a healthy granulating ulcer is left, in which the reparative processes go on briskly. The disease is thus fairly burnt out in the same manner that a phagedenic ulcer may be sometimes exterminated by the application of a caustic.

ARREST OF DEVELOPMENT OF BOTH BONES OF THE LEG.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,

Should you consider the following simple narrative of facts referring to a case which occurred in my practice, and which are sent in a true spirit of professional communication, of sufficient interest for insertion in your valuable Journal, they are quite at your service.

I remain, Sir, your obedient servant,

J. N. STEVENS.

11, Princess Square, Plymouth,

May 16, 1849.

Curious and probably unique case of an arrest of development in both bones of the leg, producing the bad effects of a supplemental joint, in which (from a different view of the cause of the unnatural state of the limb, and under the supposition that the bones had been fractured by the rough attempts of the midwife to deliver, in a footling case, and subsequent neglect of proper treatment,) it was determined, on consultation, other means having failed, to perform the operation of excision of the ends of the bones, and thus by treating the case as one of recent compound fracture, give the child the chance of preserving a useful limb, and should this plan fail, amputation was to be performed as a *dernier resort*.

CASE.

Samuel Skewes, aged $2\frac{1}{2}$ years, of healthy appearance, and good muscular development, but the child of delicate-looking parents, became a patient of mine for the first time when a month old, in consequence of an unnatural degree of motion being observable in the right leg, together with a projection of the tibia against the skin on bending the limb, from which it was evident there was a breach of continuity in the bone, and the question naturally arose, how was this state of things to be accounted for? I was immediately struck with the idea of its being a case of an arrest of development in the bone or bones, producing a kind of false joint, but on being informed that the midwife had been very rough in her attempts at delivery, the case being a footling one; and on the parents observing a certain amount of deformity in the limb a few days after the birth of the child, and pointing it out to her, she declared there was nothing of a serious nature to apprehend, and that it would

soon "*right itself again*." I began to incline to the opinion that she had been the cause of the mischief, and that I had a case of disunited fracture to manage, and acting on this idea, I well bandaged the limb, having previously placed the ends of the bones in proper apposition, and applied suitable splints, enjoining as perfect a state of rest as could be observed, for a considerable time. This request having been complied with, on the part of the parents, I removed the splints, &c., in about six weeks, but found the bones in the same unconnected state as before. I then rubbed the ends of the bones together for some time with considerable force, and reapplied the splints, &c., and at length having discovered the failure of this plan also, I determined on having a consultation on the case with two of the most eminent surgeons in the neighbourhood, who being of the same opinion as to the cause of the mischief, advised the performance of White's operation, with the hope of saving the limb; and should this fail, recommended amputation as a *dernier resort*. This being agreed on, I shortly after proceeded (having brought the child under the full influence of chloroform) to expose and saw off the ends of the bones, by making an incision of about three inches long in front of the spine of the tibia, the centre of which should correspond with the disunited end of the bones; and this having been accomplished without any pain, they were carefully exposed, and a small portion of each removed with the loss of only a small quantity of blood. The edges of the wound were brought together by adhesive straps, and a roller having been applied, the limb was placed in a small open fracture box made for the purpose, in which it was secured, and directed to be kept as quiet as possible, the friends constantly keeping watch by the child for the attainment of this object. All went on well for several days, the febrile disturbance of the system not being at all greater than might have been expected, and the suppuration that ensued continued for some time moderate, and of a healthy character; but having gradually increased in quantity, with a high degree of irritative fever and an excessively irritable state of the nervous system, with rapid emaciation and hectic, I deemed it advisable, after a period of three weeks, and in consequence of severe hæmorrhage having taken place from the wound, to resort to amputation as the only chance of safety for the patient; and having procured the necessary professional assistance, I immediately removed the limb below the knee as quickly as possible, and with scarcely any loss of blood, the popliteal artery being the only one which required a ligature. The child was again placed under the influence of chloroform for the amputation, and all went on well from this time, the boy making a good, though protracted recovery; and considering the very critical state of the child, from the failure of the first operation, with its consequent suppurative fever and hæmorrhage, I considered I had some cause for congratulation as to the issue of the case, and more particularly so, as the examination of the limb satisfactorily proved that no other proceeding could have been of any avail to my little patient, the bones having been found too small, had

they united, to support the weight of the body, their diameter at the seat of the mischief not being larger than an ordinary lead-pencil. On examining the bones, I found both tibia and fibula without ossific union, at about a third of their length from the malleoli, but having a strong ligamentous connection, the upper portions of the bones overlapping the lower; and both above and below these abnormal kind of joints, which admitted of very considerable motion, both in flexion and extension of the limb, the bones presented the appearance of having been gradually reduced in size from a short distance from their epiphyses to the ligamentous connection already mentioned, and had they been regularly filed down to the very small dimensions met with at this part of the leg, this process could not have been more effectually performed by art, whilst the portions near the knee and ankle joints were of the usual size and consistence.

Remarks.—My original impression as to the case being one of congenital arrest of development, was considered in consultation rather improbable, as the breach of continuity in the bones was so near the central point of ossification, but I consider the examination of them after the amputation was performed, to have proved satisfactorily the correctness of my first diagnosis, and the rarity of such an unusual anomaly. The irritative fever which followed the primary operation was combated by salines, with tincture of hyosciamus, an occasional mild aperient, and once or twice an anodyne at night; latterly the strength was supported by light nourishment, with a small quantity of wine, &c., &c. The effects of the first inhalation of chloroform were *most complete*, having exempted my little patient from all pain during this severe and tedious operation; it was, however, followed for some hours by considerable irritability of stomach, and slight wandering of intellect.

The excision of the ends of bones, in cases of disunited fracture, was successfully performed by Mr. White, of Manchester, more than a century and a half ago, and has been a practice occasionally adopted by others since his time; and from the supposed analogy in this case of mine, it was considered imperative to give the child the only chance of retaining a useful leg, by resorting to an operation, which, under the peculiar circumstances of his case, appeared to have been dictated by common sense, and the propriety of which surgical experience had confirmed. I believe, however, that this operation is now very seldom performed.

CLINICAL NOTES FROM PRIVATE PRACTICE.*

By WILLIAM H. RANKING, M.D., Cantab., Norwich,
Late Physician to the Suffolk General Hospital.

SUBACUTE BRONCHITIS, WITH TUBULAR EXPECTORATION FROM THE LUNGS.

The following instance of a very rare form of pulmonary disease was attended by me some time since:—

The patient, a gentleman, aged 20, was seized on awaking with a paroxysm of coughing, accompanied by expectoration of sputa, tinged with blood. He had suffered three separate attacks previous to the present, of what was looked upon as simple hæmoptysis, and as such, dreaded as the forerunner of phthisis.

The first seizure of this affection occurred in January, 1841, a second in February, and a third in April, all of which yielded to digitalis. The present attack came on unexpectedly, the patient having the day before been in his usual health. The expectoration consisted of masses, which upon casual examination appeared to be mucus, tinged with blood, and was expelled rather by "hawking" than by cough. Upon more minute inspection these sputa were seen to consist of a whitish membrane, distinctly tubular, and accurately moulded to the form of the bronchial tubes, even to their most minute ramifications. The consistence of these varied; in some portions the membrane was tough and opaque, in others thin, and raised by air into minute vesicles. The blood was small in quantity, and could be easily removed from these tubes by agitation in water.

There was little disturbance in the system beyond that produced by mental agitation, the appearance of the blood having given rise to the greatest anxiety both to the patient and his friends. The pulse was 80, and soft; the skin cool, and tongue natural; and there was little or no pain in the chest. I made a very careful stethoscopic examination relative to the existence of tubercular deposit, but could not discover any grounds of apprehension. The chest was of an unusually round figure, and gave a clear sound on percussion throughout. The respiratory murmur was of an intensity almost puerile, and audible everywhere, with the exception of the neighbourhood of the larger tubes, where it was marked by a sibilous rale. There was considerable præcordial dulness, and extensive but not forcible impulse. There was less difference than natural in the "*timbre*" of the first and second sounds. "The diagnosis I formed from these signs was, subacute inflammation of the bronchial mucous membrane, with plastic secretion; many tubes obstructed partially by membranous deposit; and a dilated heart of less than average power."

Under the impression that digitalis, which had been prescribed on former occasions, was not suitable to the state of the heart, I gave him internally the acetate of lead, guarded in the usual manner by acetic acid draughts. Aperient medicine had been exhibited before my visit. Externally to the chest I applied the Unguent. Acet. Potas. Tart. The acetate of lead was suspended after forty-eight hours, and eight-grain doses of alum were substituted.

Under this treatment considerable amendment was perceptible on the third day, and by the end of the third week every unpleasant symptom had vanished.

The patient now remains in average health, and improves daily under a generous diet, and the daily use of tepid salt-water sponging, followed by friction with horse-hair gloves. Upon every tendency to catarrh

* Continued from page 125.

he applies the *Linimentum Terebinthinae* to the chest.*

REMARKS.

The secretion of a membranous substance by the pulmonary mucous membrane is familiar to every one, as it occurs in croup; in fatal cases of which disease the bronchial tubes are often found to be filled with the same plastic material as is furnished by the lining membrane of the trachea. But the production of membranous secretion in the lungs of the adult, and unconnected with tracheal disease, must be considered as a rare event.

We have, however, several instances on record, by Bartholini, Ruysch, Tulpus, and Morgagni, and others, under the names of bronchial polypus and bronchial worms.

Hippocrates,† also, probably witnessed something of the kind in the case of *Phericides*, whom he describes as spitting up "*γαλακτωδεις*," "white milky substances."

Dr. Bergen, of Frankfort on the Maine, has left us a description of an epidemic catarrh, accompanied by the expectoration of membranous tubes, which occurred in 1759. "*Hanc tristem experientiam in propria filia feci, in qua hoc singulare simul se obtulit phenomenon, quod ante mortem, tussi et screatu rejecerit tubulum membranaceum. Hunc tubulum judico esse portionem membranæ tubulosæ per ramos bronchiorum, durante morbo, generatæ.*"

Another case is related by Dr. Warren,‡ who is generally thought to be the first person who has given an accurate description of the disease. It will be seen, however, that he did not entertain any more concise ideas concerning it than Berger, who preceded him by many years. The case is as follows:—

A girl, aged 8 years, of strumous habits, was suddenly seized with dyspnoea and cough, which yielded to medical treatment. At the end of six weeks she had a second attack, accompanied by night sweats; the symptoms ceased upon the expectoration of what Dr. Warren calls "a large polypous concretion." The girl suffered several relapses, but was at length freed from them entirely by the formation of an abscess, connected with caries of the os calcis.

Baillie has never met with a case of what he calls "*bronchial polypus*," but had seen preparations of it.

Cheyne describes two forms of "*bronchial polypus*," one of which is evidently nothing more than the fibrinous portion of blood effused into the bronchial tubes. The instance given by Laennec, as occurring in the progress of a case of phthisis, was of the same nature.

Dr. Casper§ has published the case of a girl, aged 12 years, also of strumous constitution, who, in the course

of inflammatory catarrh, coughed up "a whitish yellow polypous body, of a tenacious character, and corresponding to the bronchial ramifications."

A case will be found in the "*Med. Repository*," vol. xviii., by Mr. Iliff, and also in a memoir read before the Royal Academy of Medicine, on obliteration of the bronchial tubes, by M. Reynaud.

A paper has also appeared on the subject in the "*Medico-Chirurgical Transactions*," by Dr. Reid, in which two cases are recorded.* Another has been published by Dr. Starr,† of Daventry, under the denomination of "*chronic croup*," and which exactly resembles the case of my patient. A girl, aged 22 years, complained of pain in the chest, with a sense of general oppression. Membranous tubes, accurately moulded to the bronchial tubes, and, as in my case, tinged with blood, were expectorated. The blood was doubtless effused from small vessels ruptured in the exertion necessary to dislodge the tenacious sputa.

Authors are far from agreeing as to the precise pathological condition of the bronchial mucous membrane which gives rise to the plastic secretion. There are two principal and opposite opinions: one, which attributes the production of membrane, instead of the ordinary more fluid secretions of inflamed mucous tissue, to the existence of a high degree of irritation; another, which ascribes the phenomenon to an excess of the albuminous constituent of the blood. The generality of writers are in favour of the first opinion; the latter is embraced, among others, by Copland.‡ The question is discussed at some length by Andral,§ by whom it is decided that a high degree of irritation is not sufficient *per se* to cause the secretion of plastic membrane, but that there must be, in addition, some special conditions of innervation or sanguification.

It appears to me that neither of these opinions is the correct one, and that the true explanation is still to be sought for. If the more frequent formation of plastic membrane in children than in adults be due to the existence of a larger quantity of albumen in the blood of the former, then ought we to see such productions the common consequence, in them, of inflammations of the mucous tissues. Such, however, is not the fact. One half, at the least, of the diseases of infancy and childhood, consist of irritations, of greater or less intensity, of the pulmonary and gastro-intestinal mucous membranes. Yet in cases only of croup and diphtherite do we see the production of plastic membranes—cases which, numerically considered, are rare.

The same objections hold good against the opinion which refers this peculiar secretion to the intensity of the vascular excitement. If the degree of irritation were the true cause of such secretion, we ought to see it more frequently among the numerous cases of bronchitis and gastro-enteritis which present themselves to our notice. In our patient, as well as in that of Dr. Starr, every symptom opposed the idea of high vascular

* Since the above notes were taken this gentleman has died, with general anasarca, and other symptoms depending upon a dilated heart. He had no return of the tubular secretion, but suffered from emphysema of the lungs, and eventually from oedema, coexistent with the general dropsical symptoms.

excitement; yet was the formation of the membrane of the most perfect kind.

It is, however, in this as well as in many other points connected with the science of medicine, more easy to frame objections to a given opinion, than to propound

a better; nor in the present instance do I pretend to do so. All that can be said is, that the case may be regarded as subacute bronchitis; but why fibrinous, rather than mucous secretion, should take place, remains a mystery.

A Biographical Notice

OF

ROBERT JAMES NICHOLL STREETEN, M.D., F.L.S.,

Secretary to the Provincial Medical and Surgical Association, and Editor of this Journal.

One principal object originally contemplated in the formation of the Provincial Medical and Surgical Association, was to elevate the character of the members of the profession resident in the provinces, and by a more systematic combination, for the advancement of medical knowledge, to render their labours more productive to the treasury of science. To effect this, and in a manner in some degree commensurate with the importance of the occasion, it was found necessary that a regular plan should be devised, by which the daily occurring medical facts should be collected together, and that provincial practitioners should have a ready mode by which they could give their thoughts and opinions to the world. This important enterprize could not be successfully carried forwards without encountering great difficulties, because its very novelty rendered it impossible that those who engaged in it could have any precedents for their guidance. The scheme originally devised at Worcester, in 1832, did not provide for more than the publication of an annual volume of "Transactions," which it was very soon found was a very inadequate representation of the active and energetic spirit of inquiry which has of late years characterized the enlightened cultivators of medicine exercising their art in the English provinces. In a few years after the institution of the Association it became apparent, that a medium of communication published at more frequent intervals was positively necessary ere the object the society contemplated could be accomplished. It was not, however, until the year 1840, that any effort was made to bring about this good purpose; and but for the ready aid of one whose irreparable loss the Association will long have to mourn over, we should in all human probability have remained for an indefinite period vainly endeavouring to produce so desirable a result. But, fortunately, we possessed in our highly esteemed Secretary Dr. Streeten, one whose habits and pursuits peculiarly qualified him to foster the energies of the profession in the provinces; and whose zeal, learning, and sterling worth prompted him to do all in his power to call forth these results,

In accordance, then, with the desire to do honour to one who has been a successful cultivator of science, and who, by his life and conversation, has done much to produce a favourable impression of the medical

character on the public mind, we proceed to throw together some reflections on the life of the late Editor of this Journal.

Robert James Nicholl Streeten was born on the 28th day of June, 1800, and was the eldest of eight children. His father, John Mitchell Streeten, being at the time of his birth a resident in London. His childhood calls for no comment, excepting that his early education was carried on at home under the direction of his father; and we may infer that he was in youth well grounded in languages, ancient and modern, as in after life, he shewed very great knowledge in this department, particularly in Greek, Latin, Hebrew, French and German. We know nothing as to the circumstances which determined the choice of his profession, but find that he matriculated at Edinburgh University in the year 1820, where he remained till the year 1822. He then went to Paris, and remained there until the year 1823, after which he returned to Edinburgh and graduated in 1824. His diploma is dated on the 2nd of August in that year, his thesis being "*De delirio tremente.*" In that celebrated University he formed acquaintance congenial to his habits and pursuits, and was so fortunate as to be noticed by the late Professor Graham, to whom, in conjunction with the late Dr. Hope, he became clinical clerk; and the intercourse with the latter, thus occasioned, ripened into friendship, which continued uninterrupted until the death of that distinguished pathologist.

Professor Graham seems to have become very much attached to his pupil, as we have now lying before us a recommendatory letter from the former, on the occasion of the latter becoming a candidate for the office of Physician to the Worcester Infirmary, in which he addresses Dr. Streeten in terms of the warmest friendship, and expresses much anxiety for his future prosperity. It is worthy also of notice, that it was to his intimacy with the Professor, whom he accompanied on a walking tour to the Highlands, that the subject of this memoir first derived his taste for botany, and for the general pursuit of natural science.

Not many months after he became a physician, his father being then resident in the neighbourhood of Worcester, Dr. Streeten commenced practice in that ancient city. He was soon favourably known and

respected by his medical brethren there resident, and was elected one of the Physicians to the Dispensary. Here he had an opportunity of displaying his skill in the treatment of disease, and it proved of a high order. His connection with the Dispensary continued till his decease, and his friends have the consolation of reflecting, that his mild and amiable deportment to the sick poor so endeared him to his patients that they will long deplore the loss they have suffered.

Dr. Streeten's first contribution to medical literature was communicated to the *Midland Medical and Surgical Reporter*, a periodical which may be said to have been the forerunner of the Provincial Medical Association, and of which the first number was published at Worcester in the year 1828. Dr. Hastings, in his Address at the Worcester meeting, when the Provincial Medical and Surgical Association was formed, says of the *Midland Medical and Surgical Reporter*—"Four years experience in conducting that work has convinced those who were engaged in it, that provincial labourers are neither few, nor of small value, and the knowledge of this fact was the circumstance which induced us to consider that the more extended enterprize on which we are this day entering, was not only feasible, but would almost certainly be crowned with success." In the early deliberations concerning the constitution of the Provincial Association, Dr. Streeten took part. He was present at the first meeting, and was placed on the Worcester Council, of which he continued an active member until he died. Indeed it was soon apparent that he possessed just the talent and industry that were required in any one who would aspire to manage the affairs of an Institution, which in a few years spread its branches into every part of England, and whose members were anxious for the advancement of medical literature. A paper, published by him in the first volume of the "Transactions," illustrates the peculiar bent of his investigations, it is entitled "A Report of the State of Disease in the City of Worcester, during the Year 1832, with a Summary of the Atmospheric Phenomena during the same period." This paper constitutes a very valuable statistical document, and contains much precise information relative to the diseases prevalent in Worcester in that eventful year when the spasmodic disorder cholera appeared in that city. For the task he undertook the writer was well qualified, for he had nobly and gratuitously devoted himself to the service of the public by becoming Secretary to the Board of Health, constituted at that time in Worcester, and the indefatigable and able manner in which he performed those arduous duties was the theme of general admiration.

The next occasion which called forth Dr. Streeten's energies was, after the epidemic influenza prevailed in 1837. At that time the Council of the Provincial Association issued a circular to the members, containing inquiries respecting its rise and progress in various localities where the members resided. In reply to these inquiries a great many communications were sent, but it was manifest that without some competent person would take the trouble to arrange those replies, and deduce from them the conclusions they legitimately

supported, comparatively little advantage would result from the returns thus collected. The subject of this memoir undertook this task with alacrity, and produced a report which at the time was considered of great value; and no one can now refer to that document, as published in the sixth volume of the "Provincial Transactions" without being struck with the lucid manner in which a great mass of information respecting the spread of the epidemic influenza of the year 1837 is there laid before the public; and they must at the same time admit, that the mode of inquiry thus instituted by the Association, was productive of much benefit, and is worthy of imitation on future occasions.

These productions of Dr. Streeten could not fail to have a favourable influence in recommending him to the general members of the Association, as one highly qualified to carry out the objects for which the Association was formed, whilst at the same time the active manner in which he exerted himself in assisting the deliberations of the Worcester Council of the Association, by whom the publications of the Society were superintended, pointed him out to them as one in whose ability and energy they could place most unhesitating reliance. It was not long before an opportunity occurred which enabled them to put those favourable impressions to the test, for in the year 1840 Dr. Hennis Green determined on publishing a weekly periodical journal, which he was desirous to connect with the Provincial Association, and he declared his intention to advocate all those objects for which the Association was formed, and to demonstrate the possibility of aiding the efforts of the scattered members of the profession, in the manner successfully carried out by the proceedings of the Provincial Association. It was a part of his plan to show how highly he valued the Association, by requesting that one of the members of the Worcester Council would be connected with him as editor of the new publication. The Council had no hesitation from their knowledge of the ability and acquirements of Dr. Streeten, in fixing upon him as the coadjutor of Dr. Green, and on their recommendation the undertaking was commenced under the auspices of those two physicians, with the understanding that all endeavours should be used to insure continuance to the new work by the members of the Society.

We shall not dwell on the history of the *Provincial Journal*, for Dr. Streeten had little to do with its early management, he only wrote the leading articles. It was not until the year 1844 that he became the responsible Editor, having then become Secretary of the Association. To this office Dr. Streeten had been appointed at the anniversary meeting at Leeds, in the year 1843, on the retirement of Dr. Hastings and Mr. Sheppard, the former Secretaries; and when the determination of the proprietors of the *Provincial Journal* no longer to continue to publish the work was known, all eyes were turned to the Secretary, as being possessed of the necessary qualifications to conduct a weekly journal for the members of the Association, and he accepted the honourable and responsible post to which he was thus unanimously called, stating in the first leading article he wrote "The work will from this time

be exclusively the Journal of the Association, and no other interest, whether of publisher or proprietor, will be suffered to interfere. The principles on which it is intended to conduct it are precisely those on which the Association is itself founded, and embrace all those objects which are set forth in the printed prospectus sent to each member on his admission, and annually circulated with the volume of 'Transactions.' Up to this time Dr. Streeten had not confined his contributions to the *Provincial Journal*, but had occasionally written articles for Dr. Forbes in the *British and Foreign Medical Review*. Henceforward his energies were solely directed to carry out the behests of the Association in the two-fold character of their Secretary and Editor of their Journal. For this task he was admirably fitted, but still it was a greater undertaking than should fall to the care of any one individual. The correspondence alone which devolves on the Secretary of a society numbering between fifteen hundred and two thousand members, is a serious and constant tax upon a man's time. Then there are the subscriptions to be collected and looked after, the accounts to be kept, and occasionally great difficulties to be contended with in collecting arrears, and sometimes little irregularities to be corrected, which, in spite of the most careful management, will inevitably arise. The Secretary has also to endure communications not always of the most courteous kind from those who either fancy that they have, or really have, some cause for dissatisfaction; and occasionally, we regret to say it, he has to bear the disappointment arising from members who have gone into arrears refusing to pay their just debt, and in an abrupt manner leaving the ranks of the Society. Besides all this there are little infirmities of temper to be humoured in some of the members, who, in all other respects, are calculated to illustrate the profession they so ardently cultivate. It is manifest, therefore, that the Secretary is often placed in a trying position, and such as not only requires cool judgment and discretion, but also much tact and temper. The subject of this memoir was, in health, fully equal to this trying situation, but it may be doubted whether the additional labour of the Editorial department was not too much for him, seeing that in the latter capacity he had also to call forth such qualities, as judgment, calmness, discretion, and courtesy.

That these qualities were called forth, and that the late Editor was enabled by these means to produce a periodical worthy of the Association, is, in the highest degree, creditable to his intellectual and moral endowments, but that his nervous system would be shaken by such overstraining of the powers was not improbable, for Dr. Streeten was of a sensitive temperament, and keenly alive to any approach to censure. We have seen him write under observations, not always made in the best or most considerate spirit, by members at the anniversary meetings, if he considered them derogatory to the high character which his heart's desire was that the Journal should assume. The result of one of these conversations regarding the publications of the Association was the appointment of a Committee, at the anniversary meeting, at Norwich, to inquire

whether any, and what, alterations were required or desirable in the general publications of the Society.

The report of this Committee must have been highly gratifying to Dr. Streeten, as it fully recognized the importance and value of his editorial labours, and at the same time, by recommending the Journal to be published only once a fortnight, they so far diminished the weight of the responsibility which he had to encounter. They also proposed that Dr. Streeten should be assisted by some one of the members undertaking the foreign department of the Journal, which consequently has since that time been superintended by Dr. Ranking. This Committee also reminded the Association that they had a duty to perform in sending communications for the publications, and concluded in these words:—"Your Committee earnestly hope that whatever may be decided in the matter referred to their consideration, the Association will do its utmost, as a body, to promote the cultivation of the higher departments of medical inquiry, and thereby show that it has no sympathy with those who make the '*cui bono*,' (in the sense of immediate and obvious application to the healing art,) the one test of the value of any discovery. It is only thus we can hope to attain the high position to which such an important body should aspire, and do something towards rescuing our profession from the degradation into which it has been brought by an opposite course."

We believe that this report had a very salutary effect, not only in inducing many to come forward as contributors to the publication, but it also gave a firm assurance to the Editor that he would be supported in his laudable exertions by some of the best and most gifted of provincial investigators of medical science, and it convinced him that he had only to persevere in his onward course in the same steadiness and ability he had hitherto manifested, in order to see accomplished his earnest desire,—that the Journal should be worthy of the Association; and to those friends to whom his memory is dear, the reflection is consolatory that he lived to see, in the improved tone of the communications of the contributors, a realization of those glowing anticipations. From this time forward the character of the Journal, as a vehicle for conveying important medical information to the members of the Association, became more and more established, and no one who was in the habit of communicating with Dr. Streeten on the subject could fail to observe that his heart beat high with expectation of the benefits that would ultimately accrue from these combined efforts of the provincial profession, and no one could doubt that in his arduous undertaking he was supported by the conviction that his life, which was devoted to the cause of the Association, was not being spent in vain.

A year ago there was no reason to believe that he might not fairly calculate on living to see all the fore-shadowings of the future success of the labours in which he was engaged realized, for he was then a hale man, and appeared at that period to bear his work well. At the late Anniversary meeting at Bath, he was in high spirits, and nothing there occurred to damp

their ardour. When he returned to Worcester a more than usual press of business awaited him, but he got through it all without difficulty, and took a short trip afterwards.

It was not until late in the autumn that any alteration in his usual good looks and buoyancy took place. Those who were in the habit of seeing him often can now recollect that a change came slowly over him. He became more pallid and rather lost flesh. But nowhere was the alteration that was silently going on more apparent than at the Council Meetings, where, usually, he was self-possessed, and remarkably free from anything like irritability of manner; but as the winter approached, there was some difference in this respect, and his friends now feel that it was the beginning of that disease, which finally sapped the foundation of his nervous power, whose first manifestations they witnessed.

Excepting these trifling occurrences, to which the subsequent fatal event have given a seeming importance, the friends of Dr. Streeten did not observe any indication of illness until November, when he had an attack of bronchitis, from which he partially rallied. It returned, however, soon after Christmas and seemed to weaken him, and he emaciated under it; besides which, his nights were often disturbed by attacks of difficulty of breathing. There, however, really appeared nothing sufficient to awaken alarm; for the most careful physical examination of the thorax demonstrated nothing of a threatening kind. In short, the usual rules that occur in bronchial affections were alone discernible. It is worthy of remark that, throughout all the early period of his illness the action of the kidneys was profuse and the secretion pale, but chemical examination disclosed nothing more than the ordinary indications in hysterical cases. The pulse was quickened and the sounds of the heart, though natural, were heard louder than usual and over a larger part of the thorax, leading from the first to the belief, which the subject of this sketch had always entertained, that the heart was of a large size. He, however, did not give up his avocations, for he said although he was less equal than usual to his work, he felt that with a little assistance he could get on very well. So matters proceeded, and he took the usual measures which the symptoms appeared to call for. As the spring approached, no favourable change occurred, and he was strongly advised to leave Worcester for a time and give up his exertions. This he consented to do, and selected Torquay as the place of his retreat from the cares and anxieties of his position. This was early in April, and the weather proved cold and ungenial. However, his pectoral symptoms partially left him when he had been a short time at Torquay, and he became, as he thought, dyspeptic. He did not, under these circumstances remain longer at the coast, but returned to Worcester.

It was a great disappointment to his friends to find that his general appearance had become even more unfavourable during his short absence in Devonshire, and he found it absolutely necessary when he returned home to seek medical aid for a severe gastro-enteric irritation. The gastric disturbance shewed itself by

frequent nausea, anorexia, and by the little food he did take being generally rejected. Soon after his return dysenteric symptoms also set in, which harassed him exceedingly, and his strength rapidly gave way.

It was in vain, for some time, that the ordinary means were employed to combat this untoward concatenation; but two days before his death a favourable change appeared to take place; the irritability of the stomach diminished, he retained a little food, and the alimentary functions were altogether better performed. After his return home, till the very day of his death, he continued to exert himself in managing the affairs of the Association, although the superintendence of the Journal was in the hands of Mr. Walsh. On the ninth of May there was a Council meeting at his house, and he took part in the deliberations. On the tenth his friends thought him better altogether, and he himself expressed a confident hope of recovery.

These encouraging anticipations were as evanescent as a passing moonbeam; within a very short time after having expressed a hope that the disease had taken a favourable turn, he was seized with a shivering and faintness, followed by spasmodic pain in one thigh, and he expired almost in a minute.

A careful examination of the body was made, and the following morbid appearances were displayed:—

Worcester, May 11th, 1849.

Examination of the body of Dr. Streeten twenty-one hours after death.—There was no appearance of decomposition; the general surface of the body very pallid. On making the incision in the parietes of the thorax and abdomen a thick layer of fat was observed; about half a pint of serous fluid in the cavity of the abdomen; the lungs collapsed on opening the thorax; about half a pint of serous fluid in each sac of the pleura; the lungs quite healthy; about an ounce of fluid in the pericardium; no adhesion between it and the heart, but there was fibrinous deposit in the left ventricle, and especially in the course of the coronary arteries; the heart was healthy in structure, and the valves were particularly so; the heart was at least one-fourth larger than the average; there was hypertrophy of the left ventricle; the right ventricle was enlarged, and rather flabby; the opening between the right auricle and ventricle was large; the blood on the right side of the heart was fluid, and these cavities were rather empty. The liver seemed larger than natural, and its vessels were congested, but there was no structural change. The gall-bladder was much distended with bile. The spleen healthy, but large. The left kidney was of very small size, and surrounded by much fat; there was also thickening and hardness of the membrane lining the pelvis and the uriniferous tubes; there was no granular degeneration; the right kidney was of natural size, and the pelvis and uriniferous tubes were not so much thickened. There was a good deal of fat covering the intestines, and in the mesentery. The stomach, when opened, was found much distended with flatus; the mucous membrane of the cardiac end of the stomach was much congested with blood, which was extravasated in patches, and the whole surface was of a reddish-brown colour; the rugæ were particularly dark; there was no ulceration, and the pylorus was healthy. The same state of mucous membrane, though

not to the same extent, was continued in the duodenum, and also throughout the greater part of the small and larger intestines.

CHARLES HASTINGS.
WALTER JONES.
J. H. WALSH.
HENRY DAVIS.

It appears then that the disease under which all the powers of the system succumbed, was essentially one of the mucous membranes. It seemed to commence as influenza, and at first only to involve the bronchial surface, but after remaining in that organ for some time, and much disturbing the important functions performed by the lungs, the inflammatory action changed its seat, and that part of the mucous texture subservient to alimentation became extensively affected. The nutrition was still thus much interfered with, and the supply of new blood must have been very trifling. The heart, although not diseased, was larger than ordinary, and the right side was rather flabby. It can be readily understood, with such a state of things, how a sudden fainting fit might produce death, and we believe that such was the catastrophe which deprived our Society of one of its most honoured and useful associates.

We may here close this imperfect notice of one, whose bright career of honourable exertion was thus suddenly terminated, long ere the period of the sear and yellow leaf had arrived, and apparently before the sheaves of the harvest had been gathered in; but we must not forget shortly to advert to the fact, that as a citizen, Dr. Streeten was animated by an ardent desire to serve his generation, and that the community amongst whom he lived, will long have to regret the loss of one, who on all occasions was ready to step forward for the advancement of sound knowledge, and for the intellectual and moral improvement of the people with whom he dwelt. This induced him to lend his aid to the literary and scientific institutions in the city of Worcester, but to none more conspicuously than to the Worcestershire Natural History Society. Those who are acquainted with the early history of our Association will doubtless bear in mind, that in the first volume of its "Transactions," Dr. John Conolly published "A Proposal to establish County Natural History Societies for ascertaining the circumstances in all localities, which are productive of disease or conducive to health." In the course of his remarks on the advantages of these societies, Dr. Conolly observes, "out of the County Natural History Societies there could hardly fail to arise one more advantage which did not enter into my first consideration of them. The gradual concentration in *County Museums*, of a great part of the valuable collections already made by scientific individuals, or which would naturally be made in the course of the particular labours of several of the sections, the difficulty which individuals find in becoming even tolerably acquainted with the geology, botany, and natural history of their own county would thus in a great measure be removed; its products and manufactures would become familiar to every eye, and its history and antiquities to every mind. A tour

through the provinces of England and Scotland might then become a tour of science as well as of pleasure, and the peculiarities of our island displayed in numerous scientific collections, would attract distant and even foreign visitors." After mature deliberation it was determined to endeavour to carry out this admirable scheme in the county of Worcester, and the circumstance that Dr. Streeten was known to have given much attention to such inquiries, pointed him out as particularly qualified to assist in forming such an institution in Worcester. He cordially entered into the undertaking: he became one of the curators to the infant museum, and never failed as long as health was vouchsafed him, to give part of his time to forward these pursuits, and always regarded them as being so intimately connected with the science of medicine, that no well-educated practitioner should neglect their study.

Dr. Streeten had his reward in seeing the plan for establishing a museum, in connection with the Worcestershire Natural History Society, answer far beyond the anticipations of those who engaged in it, and it was with him a matter of great satisfaction that considerable additions to, and improvements of, the museum had been going on for some months previous to his death, which he had an honest pride in believing would be completed before the anniversary meeting, at Worcester, and would be viewed by the members there assembled with unmixed gratification.

Thus then it will be apparent, to all who reflect on what has been said of the subject of this memoir, that he was actuated by no sordid or selfish motives; "*nil humani a me alienum puto*" he might have taken as his motto, and one might well enlarge on this part of his character, but we must rather touch upon these points than enter into details; neither can we do justice to Dr. Streeten's private worth, which shone brightly in its home duties, and rendered him dear to those who were closely united to him. Those also who were intimately connected with him by the ties of friendship can testify the warmth and sincerity of his attachment, and his undeviating desire to be kind and useful to them. In his intercourse with his patients he was actuated by a constant desire to relieve their sufferings and anxieties; and he exercised his skill as a physician with so much ability, kindness, and urbanity, that he secured the confidence and attachment of those who confided themselves to his care. He made the golden rule, to "do as he would be done by," the guide of all his actions, and we doubt not that throughout his brief pilgrimage he was actuated by higher motives and aspirations than those which spring from the conventional rules that the mere worldling is too apt to regard as the controllers of his destiny, for he had thought deeply on the great truths of revealed religion, and they had shone forth in his life.

One who anxiously watched him in his illness, and tenderly administered to his relief, thus writes concerning these things:—

His first fee was a bible, given him by an old gentleman in Edinburgh, soon after he had taken his degree; it was a book which he had before that learned to value,

though it was not till some time after that he fully appreciated its worth, still it must have been grateful to him, and perhaps an important step in his after career, to have been thus reminded, as it were, that in entering upon a profession which is commonly, though very unjustly, said to have a natural tendency to infidelity, he should constantly endeavour to live unto Him whose hand he could not fail to recognize in the construction

of a frame so fearfully and wonderfully made as that of man, which was henceforth to be his study. We need scarcely say, that the hint thus given to him was not lost sight of in his after life, the last action of which was, to carry that sacred book up with him on retiring, as he then thought, to rest for the night, though in reality to enter upon an eternal rest—the rest that remaineth for the people of God.

PROVINCIAL

Medical & Surgical Journal.

WEDNESDAY, JUNE 13, 1849.

It is far from being our wish to undervalue the benefits that might be obtained through the instrumentality of judicious sanitary regulations, or to say a word that could tend to check the progress of rational philanthropy; but we think that while it is our duty to avoid apathy and depreciation on the one side, it is equally our duty to avoid enthusiasm and unreasonable anticipations on the other. There is a proneness to exaggeration in the English character—a liability to be carried beyond the boundary of common sense with reference to some favourite scheme—an inclination to regard as essential what may only be auxiliary, and to attribute omnipotence to causes which may, in reality, be capable of exerting only a partial amount of efficacy.

We trust that we are perfectly cognizant of the advantages that would arise from a system of universal drainage, ventilation, and cleanliness, and we admire the zeal which has been displayed by some members of our profession on behalf of sanitary legislation; but we fear that *too* favourable an impression has been given to the public mind concerning the beneficial results that may be expected to accrue.

Differences of opinion necessarily exist upon this as upon every other question, whether medical or non-medical, that can engage the thoughts. Some of our brethren are disposed to view the subject with less sanguine hopes than others; they give a more prominent place to what they believe to be more prolific sources of injury than want of *atmospheric* salubrity; they have carefully deliberated upon the well established, but too frequently neglected fact, that “man cannot live upon air.” They think that *due* weight has not been attached to the baneful influences of *poverty* and *vice*.

When called to estimate the causes of mor-

talidity, it is evidently most important that these destructive agents should be accurately appreciated, and we now briefly refer to this topic for the purpose of drawing special attention to its consideration.

Our own observations of disease have led us to the conclusion that draining, ventilation, and cleanliness, are utterly inadequate to achieve that grand amelioration in the physical condition of our population which is, by *many* parties, so confidently anticipated. Our conviction is, that starvation, intemperance, and exposure to cold, are far more powerful instruments in the production of disease and death, than are burial grounds, piggeries, and cess-pools; nor do we think that any permanent diminution of sickness and fatality will be ensured, among the poorer classes, so long as they seek in vain for the requisite supply of their daily sustenance, and wander well-nigh garmentless upon the winter's ice, and become emaciated under the direful tyranny of debauchery and drunkenness.

There is another item in the catalogue of morbid causes that must not be overlooked, namely, the impurity of the *internal* atmosphere. Acts of Parliament may, to a considerable extent, lead to the modification of the *external* air,—by the removal of nuisances, the pulling down of hovels, and more wholesome distribution of the dead—but they will not prevent the huddling together of the needy in dirty and contracted rooms; and are we not justified in believing that much more serious disease continually arises from this herding of the destitute, particularly when any infectious malady is introduced, than from the effluvia of church yards or ill-regulated drains?

We recommend to the perusal of our members the Reports of the Committee of the College of Physicians, in Edinburgh, appointed to consider Bills for the improvement of the health of towns; it is a pamphlet deserving attention. The following extract is copied from it:—

“All that these sanitary measures can effect, will not purify the air of the interior of the crowded rooms, inhabited by the dissipated and improvident poor, or

by the destitute poor, or do more than diminish the variety of disease and suffering which may be ascribed in part to the impurity of that air. And although much may be done by religious and moral instruction, by an enlightened and general system of improved secular education, especially as addressed to those who stand most in need of sanitary improvement, and by the well-regulated relief of destitution, to correct the evils which spring from dissipation or from indigence, yet it is only necessary to advert to the great mass of suffering permanently included under the name of the Irish poor, in every large town in this country—to the effects of stagnation in trade in any of the manufacturing districts—or, to the faulty construction of large portions of such a town as this, (Edinburgh,) which are private property and cannot be rapidly altered, in order to perceive that any such measures, for a long time to come, can only be partially successful."

Review.

On Cancerous and Cancroid Growths. By JOHN HUGHES BENNETT, M.D., F.R.S.E., &c. Edinburgh: Sutherland and Knox. 8vo. pp. 260. With One Hundred and Ninety Illustrations, copied from Nature, and Drawn on Wood by the Author.*

IV. GENERAL PATHOLOGY.—Under this head the author treats of the origin, growth, and degeneration of cancers.

Origin.—The filaments, cells, and fluid, which together make up the tissue called cancerous, originate in coagulated exudation. This is poured out exactly in the same manner as all other forms of exudation. When first perceptible it consists of a firmly molecular and granular matter, in which the cancer cell arises as in a blastema. While part of the exudation passes into cells, another portion passes into fibres, exactly in the same manner as takes place during the healing of an ulcer or wound. The filaments and fibres so formed are interlaced among the granules and cells of the blastema, to constitute the stroma of the growth, the form and density of which is dependent on the number and arrangement. Why a cancerous should differ from an inflammatory or a tubercular exudation, we are ignorant; but every kind of reasoning must lead us to the conclusion that it depends on the inherent composition or constitution of the exudation itself. On comparing the phenomena which accompany these three forms of exudation, the author points out, that, taking the products of simple inflammation (say pus) as a standard, the cell development of tubercle is below, and that of cancer above it, in the scale. One is deficient in power of development, the other possesses this power in excess. Taking all the circumstances into consideration, it seems to him probable, that tubercle is connected with some derangement in the function of the primary, and cancer with some derangement in the function of the secondary, digestion. He further points out, that whilst either of them may be found accompanied or alternate with a simple exudation, they are never met with together.

Growth.—Cancer cells and nuclei, with fibrous tissue, being produced in the manner described, the former propagate themselves. The old cell walls dissolve or break down, and the included cells or nuclei are liberated, and give rise to others in turn. The blastema necessary for this purpose is at first obtained from the original exudation poured out; but after a time, as the fibrous tissue increases, new vessels are formed in it, which continue to furnish materials to the new growth in the same manner as the old vessels furnish materials of growth to the old tissues. Notwithstanding the property inherent in the exudation itself, formerly alluded to, pathologists are obliged to acknowledge that a tissue once formed and furnished with blood-vessels, possesses the property of exerting a species of selective vital attraction on the blood, whereby such matters are transuded through the capillaries, as are readily transformed into a substance like itself. Hence, why a cancerous tumour increases by growth, which tubercle cannot be said to do.

A cancerous growth once formed may increase slowly or rapidly. The more cells it contains, the more rapidly it increases. When ulceration takes place, the cell-element, restrained until that moment by the pressure to which it was previously subjected, rapidly throws out crowds of cells, forming fungoid masses on the free surface. Internally, the cells may push their way into, and infiltrate themselves among the neighbouring tissues, which then also become cancerous, and thus the disease extends from one texture to another. In protracted cases, chains of lymphatic glands are affected, and often form separately or collectively large tumours, which, in their turn, serve to convey the disease to other textures. In the opinion of the author, the cachectic appearance, which accompanies the progress of the disease, is not connected with the cause, but is rather a result of the perverted nutrition it occasions. That cancer can be communicated by contact or inoculation is certainly opposed to experience, and the experiment of Langenbeck is not sufficient to establish this.

Degeneration.—Cancer declines, degenerates, and dies like all other vital formations, but, like them, it leaves germs which perpetuate its growth, so long as they receive nourishment. Sometimes this process receives a check from the cells, which are the agents of growth, being rendered abortive, and the result may be—1st, a fibrous cicatrix; 2nd, a fatty mass; or 3rd, a calcareous concretion.

However seldom the healing of cancer by cicatrization may be known to have happened, that it occasionally does so cannot be doubted, and Dr. Bennett gives several facts which render it probable that this is of more frequent occurrence than is generally supposed. One of the most common modes in which cancer becomes fatty, is by the transformation of its cells into compound granular corpuscles, constituting the reticulum described by Müller. It may also shrivel up, and be converted into a calcareous mass exactly in the same manner as an inflammatory or a tubercular exudation. Facts recorded in the first part of the work, afford, in the opinion of the author, unequivocal proof that a cancerous growth may undergo a spontaneous cure, and he feels persuaded, that when evidences of this result are more diligently sought after than they have hitherto been, it will be found to

* Continued from page 300.

have occurred much more frequently than is generally supposed.

V. STATISTICS.—The author is of opinion that, as exact observations accumulate, the most important results will be obtained by applying the principle of statistics to cancer. In the present state of science, however, he denies that we possess a sufficient number of these to serve as a basis for such an inquiry. According to him, there are only 526 cases of morbid growths on record, in which the structure has been carefully examined, and these include all kinds of tumours, cancerous and canceroid, in all kinds of localities and tissues. Our data, therefore, are not sufficient to render an analysis of them desirable.

VI. DIAGNOSIS.—The symptoms of cancer have been frequently found insufficient for the purposes of diagnosis; but physical signs, once established and ascertained, are, in *conjunction with these*, of universal value. The only physical method of examination to be depended on is by means of the microscope. The author takes great pains to point out, not only in this chapter, but in the preface and several other places, "that this instrument is not in itself capable, even in the most expert hands, of doing anything; but, conjoined with a knowledge of the symptoms, progress of the case, form and appearance of the morbid growth, it offers us an additional and most valuable means of prosecuting our inquiries. It is from an union of all these circumstances, combined with a minute examination of the growth, under such magnifying powers as will clearly display its cells and other primary elements that we ought to found a diagnosis, and not from one or the other separately." He further observes that "it should not be forgotten, that the whole subject is yet in its infancy, although we can see clear indications of the great value it is destined one day to acquire. Hence all generalizations should be received with the utmost caution, and all statements, in a field so comparatively unknown, ought to be advanced with the utmost diffidence."

Dr. Bennett then refers to numerous figures in the first part of the work, which he considers are highly characteristic of the structure of cancer, as seen under the microscope, and he refers to doubtful cases where such structure having been made visible, has decided the diagnosis; he also contrasts the appearances observed under the microscope between cancerous and canceroid structures. But here again the want of the illustrations, to which he continually refers, prevents us from following him.

VII. PROGNOSIS.—In this chapter the author discusses two points of great practical importance,—viz., first, the supposed uniform fatality; and, second, the tendency to return of morbid growths.

The author has brought forward several facts to show that cancerous growths do not necessarily go on enlarging until they kill, but that sometimes they become abortive. From the circumstance that indolent tumours may exist in a breast or elsewhere for years, without making progress, or causing inconvenience, and after a certain time increase and exhibit great powers of development, it would appear that at first they are often purely local. In this indolent state a tumour may often be dispersed by appropriate means, and, if excised, be permanently eradicated. Truly cancerous tumours also have been

said to have been thus treated with success, but as the structure of these growths has not been examined microscopically, there is no proof of the correctness of the statement. With regard to the probability of return, it is now well ascertained, that not only cancerous, but the most innocent, growths, may return after excision. Numerous instances are on record of fatty, fibrous, and encysted growths, returning again and again, and being finally extirpated with success. Hitherto all these kinds of tumours have been too frequently confounded together by surgeons, and it is absolutely essential to obtain more accurate information, as to the relative frequency of return in them, before arriving at decided conclusions.

VIII. RATIONAL TREATMENT.—When we observe that nutrition throughout the animal world obeys certain laws, we must feel persuaded of the reasonableness of endeavouring to destroy growth, by removing or counteracting the circumstances which favour, and putting in force those, which are hostile to it. Those means which have been blindly adopted by empirical practitioners, if they fail, do so, because they act in opposition, and if they succeed, it is because they are in harmony with the rule. The only method of treatment which has been proved to possess the slightest effect, may be shown to be that which a knowledge of anatomy and pathology would have dictated. Thus a cancerous growth is a vascular structure, which consists of nucleated cells, infiltrated among a fibrous stroma, and its power of growth, extension, and re-development, depends upon the number of cells it contains. It follows, that to retard the progress of the cancer-cell, when once formed, is to retard the advance of cancer itself, and that to render it non-productive is to arrest its progress. If it be true, that a cancerous growth may, to a certain extent, be local, it follows, that the earlier it is excised the better the chance of eradication. Lastly, if the origin of a cancerous growth depend upon the peculiarities inherent in the exudation poured out, our hopes of prevention, and especially of preventing a return after excision, must depend upon our discovery of what those peculiarities are,—upon our power of obviating them, and restoring the healthy condition of the economy. The author, therefore, confines his remarks on treatment to these three points, and speaks—first, of means of retardation and resolution; second, of means of extirpation; and, third, of means of prevention.

1st. *Means of Retardation and Resolution.*—The growth of all cells in the vegetable, as well as in the animal world, is more or less dependent upon certain external circumstances which are under the control of man; thus their development is favoured by an elevated temperature, a proper supply of moisture, room for expansion, and by certain localities. The author, therefore, points out the influence which cold, dryness, pressure, and locality, exercise, as means of retarding morbid growths.

2. *Means of Extirpation.*—These are two: 1st, excision of the part; 2nd, chemical agents which destroy texture.

As regards excision, Dr. Bennett arrives at the conclusion, that, as soon as it becomes evident that means of retardation have failed to arrest the progress of the growth, an operation should be had recourse to. If early excision were more practised, he thinks that

many of the lamentable cases which occur in practice would never arise. Many tumours which need cause little alarm during youth, become more dangerous as the age advances towards 35, and from that to 50. Thus, in a young person, longer time may be devoted to the employment of retarding and preventive means, than it would be prudent to do in adult age.

Many surgeons refuse to operate in cases of advanced cancerous tumours, on the ground—1st, that cancer is in its nature incurable; 2nd, that it is cruel to inflict on a dying individual a surgical operation destined to be of no ultimate advantage; and 3rd, that such operation, if performed, would hasten the fatal termination. Dr. Bennett combats these arguments *seriatim* at considerable length, and maintains that any tumour, so long as it continues to return in the same place, should be excised. He says—"So long as a cancer remains fixed in a part which is capable of being removed, and the strength of the patient is not too much reduced, so long is the surgeon warranted to interfere." He considers that, with reference to treatment, our efforts should be directed to ascertaining the laws which regulate the return of these growths, and to this end, not only should tumours themselves be carefully examined after extirpation to ascertain their nature, but the microscope ought to be employed during an operation, to ascertain whether the neighbouring tissues contain cancer cells or nuclei. In one case he found the muscles in the neighbourhood of the tumour so loaded with cells, that at the time he prognosed the return of the disease, which, ultimately, killed the patient.

3. *Means of Prevention.*—All empirical means directed to the general treatment of cancer have failed. We are ignorant of the original cause of the disease, and rational medicine is therefore powerless; but the author thinks an observation of the phenomena accompanying it may lead us to more useful hints. He points out that tubercle is essentially different from cancer; occurs at another epoch of life; and is materially modified by the exhibition of animal oils. He suggests that an opposite line of treatment to that found useful in the one disease, is likely to be beneficial in the other. An excessive cell development, such as occurs in cancer, must be materially influenced by diminishing the amount of fatty elements, which originally furnish elementary granules and nuclei. Fat, however, is essential to a healthy nutrition, and there will always be a difficulty in so regulating ingesta as, while on the one hand we prevent such an excess of adipose formation as not to favour excessive cell growth, on the other, we may sufficiently contribute to the healthy nutrition of the tissues. The fat which is derived from the secondary digestion, however, should be diminished, by taking care that the excreting organs fully perform their functions. If a tendency to fat be an antidote to tubercle, sparseness may possibly be opposed to cancer. In the one case we should do all we can to bring the nutrition up to, and above the average; in the other down to, and below it.

These views the author acknowledges are hypothetical, but perhaps warranted by the present state of our knowledge. He thinks they lead to the following practical rule,—viz., "that in all wasting diseases caused by mal-assimilation of the primary digestion, the animal oils are directly indicated, and that in all

diseases accompanying accumulation of fatty matter, in the economy they are contra-indicated. In the first class of affections are most scrofulous and tubercular diseases in youth; in the second, cancerous diseases in adult and advanced life. But there are cases of tubercular disease, with tendency to local fatty accumulations, in which oil is injurious; and there are also cases of cancer, with emaciation from want of assimilation, in which it is beneficial."

Proceedings of Societies.

BIRMINGHAM PATHOLOGICAL SOCIETY.

March 1, 1849.

D. W. CROMPTON, Esq., in the Chair.

TUBERCULAR DISEASE OF THE LUNGS: PNEUMO-THORAX, FOLLOWED BY EMPHYSEMA OF THE LEFT SIDE: DEATH IN SEVEN MONTHS.

Mr. F. Ryland gave the following particulars of the case:—

—, aged 19, a vigorous and muscular young man, with hereditary disposition to phthisis, after the fatigue and excitement attendant upon a visit in the country, suffered from pain in the left side, cough, dyspnoea, and expectoration of dark, thick, and excessively tough mucus, with quick pulse. This was in the middle of April, 1848. He was relieved by a blister, calomel and opium at night, and antimony during the day. Still he remained weak, pulse 100, and the cough and expectoration continued. In the middle of May he went to Hampstead, near London, for change of air and scene.

He returned on the 19th of June much worse. I examined his chest, as did Dr. Evans, on the 26th. There was dulness on percussion over the left subclavian region in front, and great part of the subscapular region posteriorly. No vesicular respiration could be heard in either situation. Bronchophony existed in front. There was hectic, frequent cough, muco-purulent expectoration, loss of appetite, and strength. Cod-liver oil was tried, and seemed to suit him; he also took an anodyne at night. I went to Scarborough, and Dr. Evans kindly undertook the charge of the patient. On the 3rd of July, Dr. E. was called to him suddenly, and found that rupture of the left lung had taken place, the signs being violent pain and dyspnoea suddenly arising. The left side of the chest enlarged and tympanitic; heart felt beating on the right of the sternum, amphoric respiration, and metallic tinkling. He lies constantly on the sound side.

On the 14th of July, when I returned, the left side was still larger than the other; very resonant on percussion; no respiratory sounds heard on this side, except the amphoric breathing, and some mucous rattle in the upper and posterior part; pulse 130; respiration frequent; cough troublesome.

August 3rd. Patient more comfortable; cough and expectoration notably diminished; pulse reduced to 110. Lies mostly on his back; can lie well on the right side; cannot lie on the left. Left side contracting in size; it contains less air, but more liquid, as is shewn by percussion posteriorly, when he sits up. The amphoric

breathing still audible, but more whistling, as if the aperture of communication between the lung and pleura were contracting. Ordered to take the cod-liver oil again.

September 6th. Both sides of chest measure exactly the same. There is still a little air in the left pleura; cough better; no expectoration; pulse 100; tongue clean. He sneezes frequently, and most violently, and has done so for many days.

20th. Measure of chest the same; the left pleural cavity is now quite full; breathing 27, pulse 120 in a minute; lips and countenance ruddy. Patient comes down every day and goes out when the weather is favourable.

He continued improving till the close of October, when he was attacked by pneumonia of the right side. There was pain, with manifest and extensive dulness of the lower and posterior part of right lung, crepitus in front, rusty expectoration, and great heat of skin. The urine was scanty and high coloured; there was frequent vomiting; the debility was at the same time extreme; he could not sit up for five minutes in the day.

November 2nd. Lips and nails blueish; breathing rapid; pulse 118, and weak; great prostration. The pain in the chest, however, was less, and the expectoration lighter in colour, but still tenacious. He was treated by the administration of mild expectorants, and the application of a blister, and gradually recovered from the pneumonia.

December 4th. Patient has become much emaciated during the last month. There is great resonance on percussion and pectoriloquy under left clavicle, indicating the existence of a large cavity. Below the third rib the left side of the chest is entirely dull. The heart still beats on the right of the sternum. The patient has a good appetite, and takes eight meals a day, and two glasses of sherry.

15th. The chest measured to-day gives the right side unaltered; the left diminished three-fourths of an inch.

From this time the patient gradually declined. For about sixteen days before his death he suffered severely from pain in the left side, aggravated by coughing, or a deep inspiration, and this side of the chest attained again its former size. The breathing became more and more oppressed, and the pulse feeble, and he died on the 11th February, more than seven months after the occurrence of the rupture of the lung.

Post-mortem examination seventy-two hours after death.—Present—Dr. Heslop, Mr. Evans, and myself. Body thin, but not in the last stage of emaciation; chest an inch below the nipples measured 32 inches, and each side exactly 16 inches. On raising the sternum, the left pleural sac was found to be quite full of fluid of a sero-purulent nature, thin at the top, and becoming more loaded with shreds and masses of soft lymph, and with pus, as we got lower into the cavity. The quantity was not measured, but in the opinion of all present, there were quite eight pints. The lung occupied the upper and back part of the thorax, being fixed there by strong organized adhesions. There was one long strap-like projection from the upper lobe extending to the diaphragm and adhering firmly to it. This adhesion had,

no doubt, been contracted before the rupture of the lung took place. We found a large emptied vomica in the front of the upper lobe, and multitudes of tubercles diffused throughout the remaining portion of the lung. Most diligent and careful search was made for the opening of communication between the lung and plural sac, but it could not be found. No amphoric breathing had been heard in the patient's chest for some weeks previous to death, nor had he felt the bubbling of the air, of which he had often before complained, and I think it probable that the opening had ceased to exist. The right lung was attached to the costal pleura throughout great part of its surface. Towards the lower and back part, the lymph was thick, and some of it of recent deposit. In some of the adventitious membrane, small flattened tubercular masses were found. The lung itself was crepitous; it contained numerous tubercles in various stages, and some small cavities of the size of horse-beans.

The heart was found rather to the right of the sternum; its walls were thin and flabby, its valves healthy. The chief points of interest in this case are:—The sudden occurrence of the pneumo-thorax on the 3rd of July, (occasioned, I presume, by the bursting of the vomica into the sac of the pleura); the shock and the impediment to respiration were nearly fatal. The constitution rallied from the shock and accommodated itself to the impeded respiration. Liquid gradually accumulated in the pleura and displaced the air, as shown by percussion, and by the feeling of bubbling of air through fluid, which the patient always felt in coughing or any forced expiration. After the lapse of ten weeks, the air was all expelled and replaced by liquid. At this time both sides of the chest measured precisely the same. The inflammation of the right lung in November was a most serious complication, and nearly proved fatal; but after that was got over, some attempt at curing the hydro-thorax seems to have been made by nature, for in the middle of December the left side had diminished three quarters of an inch.

Death was eventually caused earlier than it would otherwise have occurred by an attack of pleurisy sixteen days previous to that event; for so I read the supervention of severe pain in the left side, aggravated by coughing and a deep inspiration, and attended by an increase of the quantity of liquid in the pleural cavity.

In connection with this case, Mr. Crompton referred to another case which had come under his notice, in which pneumo-thorax took place, in a young man, apparently in good health, the day after an attack of pleuritic pain. He lived for three or four months. The air in the chest soon gave way to fluid. His lungs were tubercular.

MALFORMATION OF THE HEART.

Mr. Dampier, of Westbromwich, related the following case:—

The patient was a male child $4\frac{1}{2}$ years of age. He died suddenly. Mr. Dampier examined the body under the Coroner's precept. He knew nothing of the case during life, but collected the following particulars from the friends. He was an intelligent child; blind from birth; of ordinary size and development, except some defect in the lower limbs, for he never walked, and the distal phalanges of the fingers and toes were bulbous.

His general aspect was livid; he was subject to severe attacks of palpitation of the heart and dyspnoea, and frequently passed blood by stool.

Sectio Cadaveris.—External appearance livid; lips and tips of fingers and toes, of a deep purple. There was a large quantity of serous fluid in the pleural sac. The lungs were healthy, but somewhat congested; there was some fluid in the pericardium. The heart is large, the increase of size is owing chiefly to hypertrophy of the right side; there is also a remarkable modification of form, the right side of lower border (the *margo acutus* of normal anatomy,) being much more rounded and obtuse than the left or upper border. The right auricle is dilated to three or four times its natural capacity. The foramen ovale is wide open; the tricuspid valve is thickened and fringed on its auricular surface with small vegetations; its aperture is considerably diminished in extent, admitting barely one finger. The right ventricle is greatly hypertrophied, and its cavity almost obliterated; it would not hold more than two drachms. The valves, which are of unequal development, are stretched across the narrowed canal, and joined in the centre by the union of their free borders, one of them projecting into the cavity of the vessel in the form of a nipple-shaped process, with a perforation at the apex admitting the point of a probe. The pulmonary artery is of ordinary size; the ductus arteriosus is open, and just admits a probe. The left auricle and pulmonary artery of ordinary size. Left ventricle also hypertrophied, its walls being about half the thickness of those of the right aortic valves, and aorta normal; mitral valve also.

MENINGEAL APOPLEXY IN THE BRAIN OF AN INFANT.

Dr. Heslop presented the brain of an infant, who died suddenly three days after birth.

The mother had been admitted into the General Hospital, under the care of Dr. Evans, as a case of dropsy, but on examination, proved to be pregnant. Labour came on a few days after admission. The child presented in the first position of Naegle. From great narrowing of the passages, the second stage of labour was prolonged; but the child breathed and cried vigorously the moment it was born. There was one circumstance worthy of note about the mother's previous condition, namely, her urine was moderately albuminous. The brain was highly congested, and there was considerable extravasation of blood in the substance of the pia mater. This was particularly observed on the inferior surface of the cerebellum, and in the tuber annulare. The arachnoid cavity contained a large quantity of sanguinolent fluid.

This must be considered a case of meningeal apoplexy, the commonness of which, in early life, has been lately made the subject of many and accurate observations.

PULMONARY APOPLEXY: EMPHYSEMA AND DISEASED HEART.

Dr. Heslop gave the particulars of the following case:—

Heart: its right cavities greatly dilated; auricular orifice enormously enlarged; universal emphysema of the lungs; and pulmonary apoplexy.

The patient was under the care of Dr. Eccles, whose patient he had frequently been previously, for chronic bronchitis and emphysema. He had been for some time an out-patient; but finally finding his dyspnoea increasing daily, he consented again to become an in-patient. He was admitted in an almost moribund condition; face almost black; dyspnoea intense. Severe hæmoptysis came on in a few hours, and he sank on the day of his admission. The lungs were found to be universally emphysematous; the right lung contained many masses of pulmonary apoplexy. But Dr. Heslop wished particularly to draw the attention of the Society to the heart, which exhibited very well the retrograde effects in that organ of prolonged pulmonary obstruction. It was generally enlarged; but this enlargement was principally in the transverse direction. The apex of the heart was formed by the *right* ventricle. The capacity of this ventricle was much increased, and its walls thinned. The same conditions existed in the right auricle. The right auriculo-ventricular orifice was greatly enlarged, admitting almost the entire hand. This man had been dropsical, but there was never any murmur with the heart's sounds. There can be no doubt of the great importance of attention to the condition of this orifice, but which has, perhaps, not been as fully recognized by the great body of the profession as it deserves.

A LARGE NUMBER OF SMALL IRREGULAR GALL STONES OF CHOLESTERINE.

Dr. Fletcher mentioned the case of a female, aged 45, (her sister had malignant disease of the liver,) who applied to him with symptoms of hepatic disorder; she had had jaundice at intervals. He suspected the existence of gall stones, and those now presented were passed at once soon after.

A NUMBER OF GALL STONES (TWO OF VERY LARGE SIZE) PASSED AT ONE TIME.

Dr. Fletcher also mentioned the case of a female, aged 48, seen by him in consultation with Mr. Dampier, whose symptoms were severe but were of very short duration. There had not been jaundice. The patient had never passed stones before, and she recovered very quickly. Two of the calculi were of large size, and appeared to have originally formed one stone. The largest fragment, irregularly cylindrical, was an inch in diameter. There were besides a large number of small ones, multangular. They were composed of cholesterine.

MEMORIAL TO SIR GEORGE GREY, BART.

The Memorial of the Associated Physicians and Surgeons of Shropshire and North Wales, and of other Physicians and Surgeons practising in the Provinces.

Your Memorialists, in expressing their gratitude for the laudable anxiety you have evinced to bring the question of Medical Reform to a successful issue, cannot refrain from again pointing out to you, that no adjustment of the grievances under which the profession has so long laboured will be conclusive or satisfactory, unless a just and fair system of representa-

tion is accorded to the great body of the members in their several Colleges.

And it is matter of much regret to your Memorialists, that no indication of any intention to carry this into effect appears in the scheme emanating from a Conference of the Corporate Institutions; but, on the contrary, that further arbitrary powers are to be conferred on the College of Surgeons, and its members to be dissociated from that College, in which they have acquired their diploma and title.

Your Memorialists would fain hope, that in legislating on this subject a wise government would not withhold from a body of educated men, in their respective Colleges, that boon which in Municipal Institutions has been accorded to every rate-payer in the kingdom.

Your Memorialists consider the institution of a new College of General Practitioners as a great public and professional calamity,—uncalled for in a Profession wherein the most crying evil has always been the unnecessary multiplication of Institutions, and the diversity of their several qualifications; but when it is proposed, by the establishment of such new College, to perpetuate grades and distinctions which have no existence in reality;—to confirm the monopoly and injustice of the older Institutions, and to allow them to repudiate their proper members, in order that they may become tenant occupiers of a College possessing neither a Medical nor Surgical title;—your Memorialists cannot but look upon such a scheme as pregnant with future evil, if not degradation, to the profession, and they sincerely trust you will not sanction the establishment of any such ambiguous Institution.

Your Memorialists may state with confidence, as the universal sentiment of the profession, confirmed by a host of most respectable evidence adduced before the Medical Registration Committee, and previously before the Education Committee of 1834, that no scheme of Medical Reform can be effectual or permanent, unless it provide for the efficiency and respectability of the whole profession, by securing for all the adoption of one uniform standard of education, combined with such examinations as shall be a fair test of qualification in each of those sciences, a knowledge of which may be considered necessary to the formation of a competent Medical and Surgical Practitioner.

Now your Memorialists would observe, that the scheme of the Conference comprises no such uniformity of education, but, whilst it stringently provides for the lowest grade being instructed equally in medicine and surgery, would permanently establish, if sanctioned by the legislature, the practical absurdity (as has been well pointed out in the memorial from Manchester) of the Fellow of the College of Surgeons being authorized, *without any MEDICAL examination whatever*, not only to practice every department, but further to do so with the prestige of superior rank; and would, in like manner, leave the Fellows and Associates of the College of Physicians devoid of any test of their having obtained a knowledge of the principles of surgery.

Your Memorialists therefore earnestly entreat you to counteract so gross an anomaly, by providing, in any Bill to be introduced into Parliament, such a modification of the Colleges of Physicians and Surgeons, as shall insure that all their members, of whatever grade they may be, shall undergo, in the first instance, a joint and uniform test of their qualification to practice both

in medicine and surgery; and your Memorialists consider such an arrangement not less requisite for the well-being and harmony of the profession, than for the safety of the public.

As another advantage of such uniformity of education, your Memorialists would point with pleasure to the facility which it will afford for a simple and effectual plan of registration; nor have your Memorialists any objection to the division of labour, and the consequent partition of the profession into the two classes of physician and surgeon, or again, of each of these into a higher and lesser grade; but other titles and designations, more particularly if necessitating or leading to the formation of a new college, whereby future practitioners are to be alienated from the time-honoured institutions of their ancestors, would, in the estimation of your Memorialists, not only be superfluous and uncalled for, but positively injurious.

Your Memorialists, in conclusion, are extremely anxious that no scheme, having for its object further monopoly or aggrandizement on the part of the Corporate Bodies, should obtain your approval or concurrence; but that the just requirements of the profession and the public should be embodied in a liberal and comprehensive measure of Medical Reform, based on the principles of

“Representation” for the members in their several colleges;

“Uniformity of education;” and

“Assimilation of qualification”

for like degrees and titles throughout the kingdom. Such a measure, your Memorialists conceive, would be beneficial to the public, and satisfactory to the profession.

HENRY JOHNSON, M.D., Shrewsbury,
President of the Shropshire and North Wales Association.
May, 1849.

CONVENTION OF POOR LAW MEDICAL OFFICERS.

TO THE EDITOR OF THE PROVINCIAL MEDICAL AND SURGICAL JOURNAL.

SIR,—I am desired by the Committee to request the favour of your publishing in the next number of the *Provincial Medical and Surgical Journal*, the Report of the interview with the President of the Poor-Law Board and a Deputation from the Committee, on the subject of Poor-Law Medical Relief.

I am, Sir, your most obedient servant,

HERBERT WILLIAMS,
Assistant Secretary.

4, Hanover Square, June 5, 1849.

A deputation from the Committee, consisting of Dr. Hodgkin, Chairman, Dr. Barnett, Mr. Vallance of Stratford, Mr. Ebsworth of Bulwell, Mr. Ross, Mr. Mitchell, Mr. Porter, Mr. Peter Martin of Reigate, Mr. White and Mr. Lord, the Hon. Secretary, was received on Thursday, the 24th inst., by the President of the Poor-Law Board, at Somerset House.

Dr. Hodgkin being absent on the entrance of the

deputation, the business was entered upon by Mr. Vallance, who begged that the case might be judged of, not by his feeble advocacy, but its inherent strength and justice, adding, that although he had personally little or nothing to complain of, his own Board having acted with something like liberality and fairness, he was induced to join the deputation from a thorough conviction and long knowledge of the just claims of the medical officers. After dwelling upon their very insufficient mis-called remuneration, which varied from 2½d. to 14s. 4d. per case, and shewing that the cost of drugs alone, as stated by Dr. Riggsby and Mr. Farre, is 2s. 1½d., in dispensaries, and 3s. 7d. per case in hospitals, he asked, could it ever be pretended that the medical man was paid by 2s. 6d., the country average, for attendances and medicines? He would not insult the judgment of Mr. Baines by arguing the point. It was conceded by the resolution of the House of Commons in 1838, recommending a considerable increase, also by the feeling of the House in 1844. Lord Ashley strongly and truly expressed the opinion, that the medical officers could not properly perform their duties unless they received an income suitable to the magnitude of those duties—that they ought to be able to occupy the position that belonged to them as educated men, entrusted with great, indeed fearful, responsibilities. Mr. Vallance next urged the importance of making the appointments permanent—"quandiu se bene gesserit"—and proved the fallacy and injustice of treating the union surgeon as the only officer subject to a precarious tenure of, or capricious dismissal from office. He concluded a lucid statement by somewhat adroitly, though respectfully, reminding the President, that in ancient times a potentate began his reign by an exertion of mercy or of justice—that nothing would better become his high position, or be more graceful, than his yielding, in mercy to the sick poor, fair and impartial justice to the claims of the medical officers. All that the Committee seek may be comprised in—payment proportioned to duties; permanence of appointment during good conduct; and, responsibility to professional authority.
